ENCYCLOPÆDIA BRITANNICA.

SCULPTURE.

Origin of sculpture.

SCULPTURE is the art of imitating visible form by means of solid substances, such as marble, wood, or metals. The art is one of very great antiquity, and is generally thought to have originated from idolatry, as it was found necessary to place before the people the images of their gods, to enliven the fervour of their devotion. The pyramids and obelisks of Egypt, which were probably temples, or rather altars, dedicated to the sun, were covered with hieroglyphical emblems of men, beasts, birds, fishes, and reptiles, at a period prior to that in which there is any unexceptionable evidence that mere statue-worship prevailed even in that nursery of idolatry.

But though it appears thus evident that picture-writing was the first employment of the sculptor, we are far from imagining that idolatrous worship did not contribute to carry his art to that perfection which it attained in some of the nations of antiquity. Even in the dark ages of Europe, when the other fine arts were almost extinguished, the ceremonies of the Church of Rome, and the veneration which she taught for her saints and martyrs, preserved among the Italians some vestiges of the sister arts of sculpture and painting; and therefore, as human nature is everywhere the same, it is reasonable to believe that a similar veneration for heroes and demigods would, among the ancient nations, have a similar effect. But if this be so, the presumption is, that the Chaldæans were the first who invented the art of hewing blocks of wood and stone into the figures of men and other animals; for the Chaldæans were unquestionably the first idolaters, and their early progress in sculpture is confirmed by the united testimonies of Berosus, Alexander Polyhistor, Apollodorus, and Pliny, not to mention the eastern tradition that the father of Abraham was a sculptor.

Mr Bromley's theory that sculpture was invented by the Scythians.

Against this conclusion, however, Mr Bromley, in his History of the Fine Arts, has urged some plausible arguments. In stating these, he professes not to be original, or to derive his information from the fountain-head of antiquity. He adopts, as he tells us, the theory of a French writer, who maintains, that in the year of the world 1949, about three hundred years after the deluge, the Scythians under Brouma, a descendant of Magog the son of Japhet, extended their conquests over the greater part of Asia. According to this system, Brouma was not only the civilizer of India, and the author of the Brahminical doctrines, but also diffused the principles of the Scythian mythology over Egypt, Phœnicia, Greece, and the continent of Asia.

Of these principles Mr Bromley has given us no distinct enumeration; the account which he gives of them is not to be found in one place, but must be collected from a variety of distant passages. In attempting therefore to present the substance of his scattered hints in one view, we shall not be confident that we have omitted none of them. The ox, says he, was the Scythian emblem of the generator of animal life, and hence it became the principal divinity of the Arabians. The serpent was the symbol of the source of intelligent nature. These were the common points of union in all the first religions of the earth. From Egypt the Israelites carried with them a religious veneration for the ox and the serpent. Their veneration for the ox appeared soon after they marched into the wilderness, when, in the absence of Moses, they called upon Aaron to make them gods which should go before them. The idea of having an idol to go before them, says our author, was completely Scythian; for so the Scythians acted in all their progress throughout Asia, with this difference, that their idol was a living animal. The Israelites having gained their favourite god, which was an ox, not a calf, as it is rendered in the book of Exodus, next proceeded to hold a festival, which was to be accompanied with dancing; a species of gaiety common in the festivals which were held in adoration of the emblematic *urotal* or ox, in that very part of Arabia, near Mount Sinai, where this event took place. It is mentioned too as a curious and important fact, that the ox which was revered in Arabia was called *Adonai*. Accordingly Aaron, announcing the feast to the ox or golden calf, speaks thus, *To-morrow is a feast to Adonai*, which is in our translation rendered *to the Lord*. In the time of Jeroboam we read of the golden calves set up as objects of worship at Bethel and

Dan. Nor was the reverence paid to the ox confined to Scythia, to Egypt, and to Asia. It extended much farther. The ancient Cimbri, as the Scythians did, carried an ox of bronze before them on all their expeditions. Mr Bromley also informs us, that as great respect was paid to the living ox among the Greeks as was offered to its symbol among other nations.

The emblem of the serpent, continues Mr Bromley, was marked yet more decidedly by the express direction of the Almighty. That animal had ever been considered as emblematical of the supreme generating power of intelligent life. And was that idea, says he, discouraged, so far as it went to be a sign or symbol of life, when God said to Moses, "Make thee a brazen serpent, and set it on a pole, and it shall come to pass that every one who is bitten, when he looketh on it, shall live?" In Egypt the serpent surrounded Isis and Osiris, the diadems of their princes, and the bonnets of their priests. The serpent made a distinguished figure in Grecian sculpture. The fable of Echidne, the mother of the Scythians, gave her figure terminating as a serpent to all the founders of states in Greece; from which their earliest sculptors represented in that form the Titan princes, Cecrops, Draco, and even Ericthonius. Beside the spear of the image of Minerva, which Phidias made for the citadel of Athens, he placed a serpent, which was supposed to guard that goddess.

In Egypt, as well as in Scythia and India, the divinity was represented on the leaves of the tamara or lotus. Pan was worshipped as a god in that country, as well as over the east. Their sphinxes, and all their combined figures of animal creation, took their origin from the mother of the Scythians, who brought forth an offspring that was half a woman and half a serpent. Their pyramids and obelisks arose from the idea of flame, the first emblem of the supreme principle, introduced by the Scythians, and which even the influence of Zoroaster and the Magi could not remove.

We are told that the Bacchus of the Greeks is derived from the Brouma of the Indians; that both are represented as seated on a swan swimming over the waves, to indicate that each was the god of humid nature; not the god of wine, but the god of waters. The mitre of Bacchus was shaped like half an egg; an emblem taken from this circumstance, that at the creation the egg from which all things sprung was divided in the middle. Pan also was revered among the Scythians; and from that people were derived all the emblems by which the Greeks represented this divinity.[1]

This theory erroneous.

To form conclusions concerning the origin of nations, the rise and progress of the arts and sciences, without the aid of historical evidence, by analogies which are sometimes accidental, and often fanciful, is a mode of reasoning which cannot readily be admitted. There may indeed, we acknowledge, be resemblances in the religion, language, manners, and customs, of different nations, so striking and so numerous, that to doubt of their being descended from the same stock would savour of scepticism. But historical theories must not be adopted rashly. We must be certain that the evidence is credible and satisfactory before we proceed to draw any conclusions from it. We must first know whether the Scythian history itself be authentic, before we make any comparison with the history of other nations. But what is called the Scythian history, every man of learning knows to be a collection of fables. Herodotus and Justin are the two ancient writers from whom we have the fullest account of that warlike nation; but these two historians contradict each other, and both write what cannot be believed of the same people at the same period of their progress. By Strabo[2] and Herodotus[3] they are represented as the most savage of mortals, delighting in war and bloodshed, cutting the throats of all strangers who came among them, eating their flesh, and making cups and pots of their skulls. It is not conceivable that such savages could be sculptors; or that, even supposing their manners to have been such as Justin represents them, a people so simple and ignorant could have imposed their mythology upon the Chaldæans, Phœnicians, and Egyptians, whom we know by the most incontrovertible evidence to have been great and polished nations so early as in the days of Abraham.

Taking for granted, therefore, that the Scythians did not impose their mythology on the eastern nations, and that the art of sculpture, as well as idolatrous worship, prevailed first among the Chaldæans, we shall endeavour to trace the progress of this art through some other nations of antiquity, till we bring it to Greece, where it was carried to the highest perfection to which it has yet attained. We shall then follow out the art in its decline and subsequent revivals in modern times.

The first intimation that we have of the art of sculpture is in the book of Genesis, where we are informed, that when Jacob, by the divine command, had returned to Canaan, his wife Rachel carried along with her the teraphim or idols of her father. These we are assured were small, since Rachel found it so easy to conceal them from her father, notwithstanding his anxious search. We are ignorant, however, how these images were made, or of what materials they were composed. The first person mentioned as an artist of eminence is Bezaleel, who formed the cherubim which covered the mercy-seat.

1.—EGYPTIAN, PHŒNICIAN, AND ETRURIAN SCULPTURE.

Egyptian sculpture.

The Egyptians practised the art of sculpture very extensively; and the number and variety of their works remaining, from the most rude to the most perfect in execution, give us reason to believe we have specimens of their earliest as well as latest productions. Two circumstances appear to have obstructed the progress and advancement of the art in Egypt. First, the persons of the Egyptians were not possessed of the graces of form, elegance, or symmetry; and consequently they had no perfect standard on which to model their taste. They resembled the Chinese in the cast of their face, and in the clumsy rounding of their contours. Secondly, they were confined by their laws to the principles and practices of their ancestors, and were not permitted to introduce any innovations. Their statues were always formed in the same stiff attitude, with the arms hanging perpendicularly down the sides. So far were they from attempting any improvements, that in the time of Hadrian the art continued in the same rude state as at first; and when their slavish adulation for that emperor induced them to place amongst the objects of their worship the statue of his favourite Antinous, the same inanimate stiffness in the attitude of the body and position of the arms was observed.

First styl

Notwithstanding the attachment of the Egyptians to ancient usages, Winckelman thinks he has discovered two different styles of sculpture, which prevailed at different periods. The first of these ends with the conquest of Egypt by Cambyses; the second begins at that time, and extends beyond the reign of Alexander the Great. In the first style, the lines which form the contour are straight, and projecting a little; the position is stiff and unnatural. In sitting figures the legs are parallel, the feet squeezed together, and the arms fixed to the sides; but in the figures of women the left arm is folded across the breast; the bones and muscles are faintly discernible; the eyes are flat and looking obliquely, and the eyebrows sunk,—features which destroy entirely the beauty of the head; the cheek-bones are high, the chin small and piked; the ears are generally placed higher than in nature, and the feet are too large and flat. In short, if we are to look for any model in the statues of Egypt, it is not for the model of beauty, but of deformity. The statues of men are naked, only they have a short apron, and a few folds of drapery surrounding their waist. The vestments of women are only distinguishable by the border, which rises a little above the surface of the statue. In this age it is evident the Egyptians knew little of drapery.

---

[1] It would be tedious to follow our author through the whole of this subject; and were we to submit to the labour of collecting and arranging his scattered materials, we should still view his system with some degree of suspicion. It is drawn, as he informs us, from the work of M. D'Ancarville, entitled *Recherches sur l'Origine, l'Esprit, et les Progrès, des Arts de la Grèce.*

[2] Lib. vii.

[3] Lib. iv. cap. 62.

Second style.

Of the second style of sculpture practised amongst the Egyptians, Winckelman thinks he has found specimens in the two figures of basaltes in the Capitol, and in another figure at the Villa Albani, the head of which has been renewed. The first two of these, he remarks, bear visible traces of the former style, which appear especially in the form of the mouth and the shortness of the chin. The hands possess more elegance; and the feet are placed at a greater distance from each other than was customary in more ancient times. In the first and third figures the arms hang down close to the sides; in the second they hang more freely. Winckelman suspects that these three statues were made after the conquest of Egypt by the Greeks. They are clothed with a tunic, a robe, and a mantle. The tunic, which is puckered into many folds, descends from the neck to the ground. The robe in the first and third statues seems close to the body, and is only perceptible by some little folds. It is tied under the breast, and covered by the mantle, the two buttons of which are placed under the epaulette.

The Egyptian statues were not only formed by the chisel; they were also polished with great care. Even those on the summit of an obelisk, which could only be viewed at a distance, were finished with as much labour and care as if they had admitted a close inspection. As they are generally executed in granite or basalt, stones of a very hard texture, it is impossible not to admire the indefatigable patience of the artists. The eye was often of different materials from the rest of the statue; sometimes it was composed of a precious stone or metal. We are assured that the valuable diamond of an empress of Russia, the largest and most beautiful hitherto known, formed one of the eyes of the famous statue of Scheringham in the temple of Brahma.

Herodotus mentions two Egyptian statues, one placed before the temple of Vulcan at Memphis, the other in the city of Sais by king Amasis, each of which was seventy-five feet long. The colossal sphinx near the great pyramid rises twenty-five feet. The sitting statues of Memnon, the mother and son of Osmandue, at Thebes, are each fifty-eight feet high. To these we might add a number of similar works known by remaining fragments, or described by authors. Most of the great works of the Egyptians were executed in the reign of Sesostris, who lived in the time of Rehoboam king of Israel, a thousand years before the Christian era, which shows that the arts of Egypt and of Greece were in a progressive state of improvement at the same time.

The enormous works of Egypt have struck foreign visiters with wonder and awe, from Herodotus down to the members of the French Institute. Herodotus says, "one of their buildings is equal to many of the most considerable Greek buildings taken together;" and M. Ripaud observes, "these works are so prodigious, they make every thing we do look little." The Egyptians had notions of durability in their works which no other nation has succeeded in imitating: they seemed to work as if they laughed at time, war, barbarism. Quantity was every thing with them, or almost so; quality but little. They wished to please themselves and astonish posterity, and they succeeded.

The ancient authors who give the most satisfactory accounts of Egyptian antiquities are, Herodotus, Diodorus Siculus, Josephus, Strabo, Clemens of Alexandria, Jamblicus, and Orus Apollo. Among the modern writers, we may mention Pocock, Savary, Norden, and Denon, as worthy of perusal on this subject.

Phœnician sculpture.

The Phœnicians possessed both a character and a situation highly favourable to the cultivation of statuary. They had beautiful models in their own persons, and their industrious character qualified them to attain perfection in every art for which they had a taste. Their situation raised a spirit of commerce, and commerce induced them to cultivate the arts. Their temples shone with statues and columns of gold, and a profusion of emeralds was everywhere scattered about. All the great works of the Phœnicians have been unfortunately destroyed; but many of the Carthaginian medals are still preserved, ten of which are deposited in the cabinet of Florence. But though the Carthaginians were a colony of Phœnicians, we cannot from their works judge of the merit of their ancestors.

This art not cultivated among the Persians.

The Persians made no distinguished figure in the arts of design. They were indeed sensible to the charms of beauty, but they did not study to imitate them. Their dress, which consisted of long flowing robes concealing the whole person, prevented them from attending to the beauties of form. Their religion, too, which taught them to worship the divinity in the emblem of fire, and that it was impious to represent him under a human form, seemed almost to prohibit the exercise of this art, by taking away those motives which alone could give it dignity and value; and as it was not customary among them to raise statues to great men, it was impossible that statuary could flourish in Persia.

Etrurian sculpture.

The Etrurians, or ancient Tuscans, in the opinion of Winckelman, carried this art to some degree of perfection at an earlier period than the Greeks. It is said to have been introduced before the siege of Troy by Dædalus, who, in order to escape the resentment of Minos king of Crete, took refuge in Sicily, whence he passed into Italy, where he left many monuments of his art. Pausanias and Diodorus Siculus inform us, that some works ascribed to him were to be seen when they wrote; and that these possessed that character of majesty which afterwards distinguished the labours of Etruria.

A character strongly marked forms the chief distinction in those productions of Etruria which have descended to our times. Their style was indeed hard and overcharged; for it is not to be supposed that a people of such rude manners as the Etrurians could communicate to their works that vividness and beauty which the elegance of Grecian manners inspired. On the other hand, there are many of the Tuscan statues which bear so close a resemblance to those of Greece, that antiquaries have thought it probable that they were conveyed from that country, or Magna Græcia, into Etruria, about the time of the Roman conquest, when Italy was adorned with the spoils of Greece.

First style.

Among the monuments of Etrurian art two different styles have been observed. In the first the lines are straight, the attitude stiff, and no idea of beauty appears in the formation of the head. The contour is not well rounded, and the figure is too slender. The head is oval, the chin piked, the eyes flat, and looking asquint. These are the defects of an art in the state of infancy, which an accomplished master could never fall into, and are equally conspicuous in Gothic statues as in the productions of the ancient natives of Florence. They resemble so much the style of the Egyptians, that one is almost induced to suppose that there had once been a communication between these two nations; but others think that this style was introduced by Dædalus.

Second style.

Winckelman supposes that the second epoch of this art commenced in Etruria about the time at which it had reached its greatest perfection in Greece, in the age of Phidias. But this conjecture is not supported by any proofs. The joints are strongly marked, the muscles raised, and the bones distinguishable; but the whole mien is harsh. In designing the bone of the leg, and the separation of the muscles of the calf, there is an elevation and strength above life. The statues of the gods are designed with more delicacy. In forming them, the artists were anxious to show that they could exercise their power without that violent distension of the muscles which is necessary in the exertions of beings merely human; but in general their attitudes are unnatural, and the actions strained. If a statue, for instance, hold any thing with its fore-fingers, the rest are stretched out in a stiff position.

II.—GRECIAN SCULPTURE.

According to ancient history, the Greeks did not emerge from the savage state till a long time after the Egyptians, Chaldæans, and Indians, had arrived at a considerable degree of civilization. The original rude inhabitants of Greece were civilized by colonies which arrived among them, at different times, from Egypt and Phœnicia. These brought along with them the religion, the letters, and the arts of their parent countries; and if sculpture had its origin from the worship of idols, there is reason to believe that it was one of the arts which were thus imported; for that the gods of Greece were of Egyptian and Phœnician extraction is a fact incontrovertible. The original statues of the gods, however, were very rude. The earliest objects of idolatrous worship have everywhere been the heavenly bodies; and the symbols consecrated to them were generally pillars of a conical or pyramidal figure. It was not till hero-worship was ingrafted on the planetary that the sculptor thought of giving to the sacred statue any part of the human form; and it appears to have been about the era of their revolution in idolatry that the art of sculpture was introduced among the Greeks. The first representations of their gods were round stones placed upon cubes or pillars; and these stones they afterwards formed roughly, so as to give them something of the appearance of a head. Agreeable to this description was a Jupiter which Pausanias saw in Tegeum, in Arcadia. These representations were called Hermes; not that they represented Mercury, but from the word which signified a rough stone. It is the name which Homer gives to the stones which were used to fix vessels to the shore. Pausanias saw at Pheres thirty deities made of unformed blocks or cubical stones. The Lacedæmonians represented Castor and Pollux by two parallel posts; and a transverse beam was added, to express their mutual affection.

If the Greeks derived from foreign nations the rudiments of the arts, it must redound much to their honour, that in a few centuries they carried them to such wonderful perfection as entirely to eclipse the fame of their masters. It is by tracing the progress of sculpture among them that we are to study the history of this art; and we shall see its origin and successive improvements correspond with nature, which always operates slowly and gradually.

Causes which promoted the art of sculpture in Greece.

The great superiority of the Greeks in the art of sculpture may be ascribed to a variety of causes. The influence of climate over the human body is so striking, that it must have fixed the attention of every thinking man who has reflected on the subject. The violent heats of the torrid zone, and the excessive cold of the polar regions, are unfavourable to beauty. It is only in the mild climates of the temperate regions that it appears in its most attractive charms. Perhaps no country in the world enjoys a more serene air, less tainted with mist and vapours, or possesses in a higher degree that mild and genial warmth which can unfold and expand the human body into all the symmetry of muscular strength, and all the delicacies of female beauty, in greater perfection, than the happy climate of Greece; and never was there any people that had a greater taste for beauty, or were more anxious to improve it. Of the four wishes of Simonides, the second was to have a handsome figure. The love of beauty was so great among the Lacedæmonian women, that they kept in their chambers the statues of Nereus, of Narcissus, of Hyacinthus, and of Castor and Pollux, hoping that by often contemplating them they might have beautiful children.

There was a variety of circumstances in the noble and virtuous freedom of the Grecian manners, that rendered these models of beauty peculiarly subservient to the cultivation of the fine arts. There were no tyrannical laws, as among the Egyptians, to check their progress. They had the best opportunities to study them in the public places, where the youth, who needed no other veil than that of chastity and purity of manners, performed their various exercises quite naked. They had the strongest motives to cultivate sculpture, for a statue was the highest honour which public merit could attain. It was an honour ambitiously sought, and granted only to those who had distinguished themselves in the eyes of their fellow-citizens. As the Greeks preferred natural qualities to acquired accomplishments, they decreed the first rewards to those who excelled in agility and strength of body. Statues were often raised to wrestlers. Even the most eminent men of Greece, in their youth, sought renown in gymnastic exercises. Chrysippus and Cleanthes distinguished themselves in the public games before they were known as philosophers. Plato appeared as a wrestler both at the Isthmian and Pythian games; and Pythagoras carried off the prize at Elis. The passion by which they were inspired was the ambition of having their statues erected in the most sacred place of Greece, to be seen and admired by the whole people. The number of statues erected on different occasions was immense; of course the number of artists must have been great, their emulation ardent, and their progress rapid.

As most of the statues were decreed for those who vanquished in the public games, the artists had the opportunity of seeing excellent models; for those who surpassed in running, boxing, and wrestling, must in general have been well formed, yet would exhibit different kinds of beauty.

The high estimation in which sculptors were held was very favourable to their art. Socrates declared artists to be the only wise men. An artist could be a legislator, a commander of armies, and might hope to have his statue placed beside those of Miltiades and Themistocles, or those of the gods themselves. Besides, the honour and success of an artist did not depend on the caprice of pride or of ignorance. The productions of art were estimated and rewarded by the greatest sages in the general assembly of Greece; and the sculptor who had executed his work with ability and taste was confident of obtaining immortality.

It was the opinion of Winckelman, that liberty was highly favourable to this art; but, though liberty is absolutely necessary to the advancement of science, it may be doubted whether the fine arts owe their improvement to this cause. Sculpture flourished most in Greece when Pericles exercised the power of a king, and in the reign of Alexander when Greece was conquered. It attained no perfection in Rome until Augustus had enslaved the Romans. It revived in Italy under the patronage of the family of Medici, and in France under the despotic rule of Louis XIV. It is the love of beauty, luxury, wealth, or the patronage of a powerful individual, that promotes the progress of this art.

Grecian ideas of beauty.

The head.

It will now be proper to give a particular account of the ideas which the Greeks entertained concerning the standard of beauty in the different parts of the human body. And with respect to the head, the profile which they chiefly admired is peculiar to dignified beauty. It consists in a line almost straight, or marked by such slight and gentle inflections as are scarcely distinguishable from a straight line. In the figures of women and young persons, the forehead and nose form a line approaching to a perpendicular.

The forehead.

Ancient writers, as well as artists, assure us that the Greeks reckoned a small forehead a mark of beauty, and a high forehead a deformity. From the same idea, the Circassians wore their hair hanging down over their foreheads almost to their eyebrows. To give an oval form to the countenance, it is necessary that the hair should cover the forehead, and thus make a curve about the temples, otherwise the face, which terminates in an oval form in the inferior part, will be angular in the higher part, and the proportion will be destroyed. This rounding of the forehead may be seen in all handsome persons, in all the heads of ideal beauty in ancient statues, and especially in those of youth. It has been overlooked, however, by modern statuaries. Bernini, who modelled a statue of Louis XIV. in his youth, turned back the hair from the forehead.

The eyes.

It is generally agreed that large eyes are beautiful; but their size is of less importance in sculpture than their form, and the manner in which they are enchased. In ideal beauty, the eyes are always sunk deeper than they are in nature, and consequently the eyebrows have a greater projection. But in large statues, placed at a certain distance, the eyes, which are of the same colour with the rest of the head, would have little effect if they were not sunk. By deepening the cavity of the eye, the statuary increases the light and shade, and thus gives the head more life and expression. The same practice is used in small statues. The eye is a characteristic feature in the heads of the different deities. In the statues of Apollo, Jupiter, and Juno, the eyes are large and round. In those of Pallas they are also large; but by lowering the eyelids, the virgin air and expression of modesty are delicately marked. Venus has small eyes, and the lower eyelid being raised a little, gives them a languishing look and enchanting sweetness. It is only necessary to see the Venus de' Medicis to be convinced that large eyes are not essential to beauty, especially if we compare her small eyes with those which resemble them in nature. The beauty of the eyebrows consists in the fineness of the hair, and in the sharpness of the bone which covers them; and masters of the art considered the joining of the eyebrows as a deformity, though it is sometimes to be met with in ancient statues.

The mouth.

The beauty of the mouth is peculiarly necessary to constitute a fine face. The lower lip must be fuller than the upper, in order to give an elegant rounding to the chin. The teeth seldom appear, except in laughing satyrs. In human figures the lips are generally close, and a little opened in the figures of the gods. The lips of Venus are half open. In figures of ideal beauty, the Grecian artists never interrupted the rounding of the chin by introducing a dimple; for this they considered not as a mark of beauty, and only to be admitted to distinguish individuals. The dimple indeed appears in some ancient statues, but antiquaries suspect it to be the work of a modern hand. It is suspected, also, that the dimple which is sometimes found on the cheeks of ancient statues is a modern innovation.

The ears.

No part of the head was executed by the ancients with more care than the ears, though little attention has been given to them by modern artists. This character is so decisive, that if we observe in any statue that the ears are not highly finished, but only roughly marked, we may conclude with certainty that we are examining a modern production. The ancients were very attentive to copy the precise form of the ear in taking likenesses. Thus, where we meet with a head the ears of which have a very large interior opening, we know it to be the head of Marcus Aurelius.

The hair.

The manner in which the ancient artists formed the hair also enables us to distinguish their works from those of the moderns. On hard and coarse stones the hair was short, and appeared as if it had been combed with a wide comb; for that kind of stone was difficult to work, and could not without immense labour be formed into curled and flowing hair. But the figures executed in marble in the most flourishing period of the art have the hair curled and flowing; at least where the head was not intended to be an exact resemblance, for then the artist conformed to his model. In the heads of women, the hair was thrown back, and tied behind in a waving manner, leaving considerable intervals; which gives the agreeable variety of light and shade, and produces the effects of the claro-oscuro. The hair of the Amazons is disposed in this manner. Apollo and Bacchus have their hair falling down their shoulders; and young persons, until they arrived at manhood, wore their hair long. The colour of the hair which was reckoned most beautiful, was fair; and this they gave without distinction to the most beautiful of their gods, Apollo and Bacchus, and likewise to their most illustrious heroes.

The hands.

Although the ravages of time have preserved but few of the hands or feet of ancient statues, it is evident from what remains how anxious the Grecian artists were to give every perfection to these parts. The hands of young persons were moderately plump, with little cavities or dimples at the joints of the fingers. The fingers tapered very gently from the root to the points, like well-proportioned columns, and the joints were scarcely perceptible. The terminating joint was not bent, as it commonly appears in modern statues.

The legs and feet.

In the figures of young men the joints of the knee are faintly marked. The knee unites the leg to the thigh without making any remarkable projections or cavities. The most beautiful legs and best-turned knees, according to Winckelman, are preserved in the Apollo Saurocthones, in the Villa Borghese; in the Apollo which has a swan at its feet; and in the Bacchus of the Villa Medicis. The same able connoisseur remarks, it is rare to meet with beautiful knees in young persons, or in the elegant representations of art. As the ancients did not cover the feet as we do, they gave to them the most beautiful turning, and studied the form of them with the most scrupulous attention.

The breast and lower part of the body.

The breasts of men were large and elevated. The breasts of women did not possess much amplitude. The figures of the deities have always the breasts of a virgin, the beauty of which the ancients made to consist in a gentle elevation. So anxious were the women to resemble this standard, that they used several arts to restrain the growth of their breasts. The breasts of the nymphs and goddesses were never represented swelling, because that is peculiar to those women who suckle. The paps of Venus contract and end in a point, this being considered as an essential characteristic of perfect beauty. Some of the moderns have transgressed these rules, and have fallen into great improprieties. The lower part of the body in the statues of men was formed like that of the living body after a profound sleep and good digestion. The navel was considerably sunk, especially in female statues.

Ideal beauty.

As beauty never appears in equal perfection in every part of the same individual, perfect or ideal beauty can only be produced by selecting the most beautiful parts from different models; but this must be done with such judgment and care, that these detached beauties when united may form the most exact symmetry. Yet the ancients sometimes confined themselves to one individual, even in the most flourishing age. Theodorus, whom Socrates and his disciples visited, served as a model to the artists of his time.

Phryne also appears to have been a model to the painters and sculptors. But Socrates, in his conversation with Parrhasius, says, that when a perfect beauty was to be produced, the artists joined together the most striking beauties which could be collected from the finest figures. We know that Zeuxis, when he was going to paint Helen, united in one picture all the beauties of the most handsome women of Crotona.

The drapery of statues.

The Grecian sculptors, who represented with such success the most perfect beauty of the human form, were not regardless of the drapery of their statues. They clothed their figures in the most proper stuff, which they wrought into that shape which was best calculated to give effect to their design.

The vestments of women in Greece generally consisted of linen cloth, or some other light stuff, and in later times of silk, and sometimes of woollen cloth. They had also garments embroidered with gold. In the works of sculpture, as well as in those of painting, one may distinguish the linen by its transparency and small united folds. The other light stuffs which were worn by the women were generally of cotton produced in the isle of Cos; and these the art of statuary was able to distinguish from the linen vestments. The cotton cloth was sometimes striped, and sometimes embellished with a profusion of flowers. Silk was also employed; but whether it was known in Greece before the time of the Roman emperors cannot easily be determined. In paintings it is distinguishable by changing its colour in different lights, to red, violet, and sky-blue. There were two sorts of purple; that which the Greeks called the colour of the sea, and Tyrian purple, which resembled lac. Woollen garments are easily known by the amplitude of their folds. Besides these, cloth of gold sometimes composed their drapery. But it was not like the modern fabric, consisting of a thread of gold or of silver spun with a thread of silk; it was composed of gold or silver alone, without any mixture.

Vestments.

The vestments of the Greeks, which deserve particular attention, are the tunic, the robe, and the mantle.

The tunic was that part of the dress which was next to the body. It may be seen in sleeping figures, or in those in deshabile; as in the Flora Farnese, and in the statues of the Amazons in the Capitol. The youngest of the daughters of Niobe, who throws herself at her mother's side, is clothed only with a tunic, which was of linen, or some other light stuff, without sleeves, fixed to the shoulders by a button, so as to cover the whole breast. None but the tunics of the goddess Ceres and comedians have long straight sleeves.

The robes of women commonly consisted of two long pieces of woollen cloth, without any particular form, attached to the shoulders by a great many buttons, and sometimes by a clasp. They had straight sleeves which came down to the wrists. The young girls, as well as the women, fastened their robe to their side by a cincture, in the same way as the high priest of the Jews fastened his, and as it is still done in many parts of Greece. The cincture formed on the side a knot of ribbons sometimes resembling a rose in shape, which has been particularly remarked in the two beautiful daughters of Niobe. In the younger of these the cincture is seen passing over the shoulders and the back. Venus has two cinctures, the one passing over the shoulder, and the other surrounding the waist. The latter is called cestus by the poets.

The mantle was called *peplon* by the Greeks, which signifies properly the mantle of Pallas. The name was afterwards applied to the mantles of the other gods, as well as to those of men. This part of the dress was not square, as some have imagined, but of a roundish form. The ancients indeed speak in general of square mantles, but they received this shape from four tassels, which were affixed to them; two of these were visible, and two were concealed under the mantle. The mantle was brought under the right arm, and over the left shoulder; sometimes it was attached to the shoulder by two buttons, as may be seen in the beautiful statue of Leucothoe at the Villa Albani.

The colour of vestments peculiar to certain statues is too curious to be omitted. To begin with the figures of the gods, the drapery of Jupiter was red, that of Neptune is supposed by Winckelman to have been sea-green. The same colour also belonged to the Nereids and the Nymphs. The mantle of Apollo was blue or violet. Bacchus was dressed in white. Martianus Capella assigns green to Cybele. Juno's vestments were sky-blue, but she sometimes had a white veil. Pallas was robed in a flame-coloured mantle. In a painting of Herculanum, Venus is in flowing drapery of a golden-yellow. Kings were arrayed in purple, priests in white, and conquerors sometimes in sea-green.

With respect to the head, women generally wore no covering but their hair; when they wished to cover the head, they used the corner of their mantle. Sometimes we meet with veils of a fine transparent texture. Old women wore a kind of bonnet upon their head, an example of which may be seen in a statue in the Capitol, called the *Præfica*; but Winckelman thinks it is a statue of Hecuba.

The covering of the feet consisted of shoes or sandals. The sandals were generally an inch thick, and composed of more than one sole of cork. Those of Pallas in the Villa Albani has two soles, and other statues had no less than five.

Ancient style of Grecian sculpture.

The most authentic monuments of the ancient style are medals, containing an inscription which leads us back to very distant times. The writing is from right to left, in the Hebrew manner, a usage which was abandoned before the time of Herodotus. The statue of Agamemnon at Elis, which was made by Ornatas, has an inscription from right to left. This artist flourished fifty years before Phidias. It is in the intervening period therefore between these two artists that we are to look for the cessation of this practice. The statues formed in the ancient style were neither distinguished by beauty of shape nor by proportion, but bore a close resemblance to those of the Egyptians and Etrurians. The eyes were long and flat; the section of the mouth not horizontal; the chin was pointed; the curls of the hair were ranged in little rings, and resembled grains enclosed in a heap of raisins. What was still worse, it was impossible by inspecting the head to distinguish the sex. The characters of this ancient style were these: the designing was energetical, but harsh; it was animated, but without gracefulness; and the violence of the expression deprived the whole figure of beauty.

The grand style.

The grand style was brought to perfection by Phidias, Polycletus, Scopas, Alcamenes, Myron, and other illustrious artists. It is probable, from some passages of ancient writers, that in this style were preserved some characters of the ancient manner, such as the straight lines, the squares, and angles. The ancient masters, being the legislators of proportions, and thinking they had a right to distribute the measures and dimensions of the parts of the human body, have undoubtedly sacrificed some degree of the form of beauty, to a grandeur which is harsh, in comparison of the flowing contours and graceful forms of their successors.

Phidias.

Phidias, the great master of this art, was born at Athens in the seventy-third Olympiad, about 488 years B. C. He was the contemporary of Socrates, Plato, Xenophon, and other eminent men, and was engaged by Pericles to superintend the decoration of the temple of Minerva and other public works. "His superior genius," says Flaxman, "in addition to his knowledge of painting, which he practised previous to sculpture, gave a grandeur to his compositions, a grace to his groups, a softness to flesh, and flow to draperies, unknown to his predecessors, the character of whose figures was stiff rather than dignified; their forms either meagre or turgid; the folds of drapery parallel, poor, and resembling geometrical lines, rather than the simple but ever-varying appearances of nature." Quintilian says of Phidias, " his Athenian Minerva, and Olympian Jupiter at Elis, possessed beauty which seemed to have added something to religion, the majesty of the work was so worthy of the divinity." The greatest work of this chief of sculptors was the Jupiter at Elis, sixty feet in height, formed of ivory, enriched with the radiance of golden ornament and precious stones, and justly esteemed one of the seven wonders of the world.

The graceful style.

The third style of Grecian sculpture was the graceful or beautiful. Praxiteles and Lysippus introduced this style. Being more conversant than their predecessors with the sweet, the pure, the flowing, and the beautiful lines of nature, they avoided the square forms, which the masters of the second style had too much employed. They were of opinion that the use of the art was rather to please than to astonish, and that the aim of the artists should be to raise admiration by giving delight. The artists who cultivated this style did not, however, neglect to study the sublime works of their predecessors. They knew that grace is consistent with the most dignified beauty, and that it possesses charms which must ever please; they knew also that these charms are enhanced by dignity. Grace is infused into all the movements and attitudes of their statues, and it appears in the delicate turns of the hair, and even in the adjusting of the drapery. Every sort of grace was well known to the ancients; and great as the ravages of time have been amongst the works of art, specimens are still preserved, in which can be distinguished dignified beauty, attractive beauty, and a beauty peculiar to infants.

Praxiteles.

Praxiteles, a native of Magna Græcia, was born about 364 years B. C. He excelled in the highest graces of youth and beauty. " None," says a judicious writer on sculpture, " ever more happily succeeded in uniting softness with force,—elegance and refinement with simplicity and purity: his grace never degenerates into the affected, nor his delicacy into the artificial. Over his compositions he has thrown an expression spiritual at once and sensual; a voluptuousness and modesty which touch the most insensible, yet startle not the most retiring." Among the known works of this master are his Satyr, Cupid, Apollo the Lizard-killer, and Bacchus leaning on a Fawn. The famous Venus of Gnidos was also his work. This statue seems to offer the first idea of the Venus de' Medicis, the statue which still " enchants the world," and " fills the air around with beauty," and which is probably the repetition of another Venus of Praxiteles.

Lysippus.

Lysippus of Sicyon, the younger, the contemporary and rival of Praxiteles, it is believed worked only in metal. Although he is said to have executed upwards of six hundred works, not one remains. The Tarentine Jupiter, sixty feet high, was one of his great works. He excelled in the knowledge of symmetry, and many of his works were finished with the utmost delicacy and truth. He was so great a favourite with Alexander, that he alone was allowed to make casts of the prince. It gives us some idea of the high consideration in which his works were held by the Romans, that even Tiberius trembled in his palace at an insurrection of the people, occasioned by the removal from one of the public baths of a figure by Lysippus.

Existing specimens of Grecian sculpture.

The works that remain to us of ancient art sufficiently attest the excellence of the Greeks in sculpture. We can only allude very briefly to some of the most celebrated of these productions. The Apollo Belvidere, believed to be the Apollo of Calamis mentioned by Pliny, has with justice been deemed one of the most admirable works of Grecian art. This statue " breathes the flame with which 'twas wrought," as if the sculptor had left a portion of his own soul within the marble, to half-animate his glorious creation. The Dying Gladiator is another greatly-valued work, finely designed, full of truth, and admirably executed. The Fawn of the Florence Gallery, so wonderfully restored by Michel Angelo, is an exquisite and characteristic representation. The Fighting Gladiator, and several of the statues of Venus, Diana, Mercury, and Bacchus, are expressive productions of the best days of Grecian sculpture. These precious monuments of art, the ancient groups, display the sentiment, heroism, beauty, and sublimity of Greece, existing as it were before us. The Laocoon, animated with the hopeless agony of the father and sons, is the work of Apollodorus, Athenodorus, and Agesander of Rhodes. The groups of Dirce, Hercules, and Antæus, Atreus, Orestes, and Electra, and Ajax supporting Patroclus, are examples of fine form, character, and sentiment. The group of Niobe and her youngest daughter, by Scopas, is an exquisite specimen of art, replete with heroic beauty and exalted passion. The group of the Wrestlers is a representation of difficult but harmonious composition; and that of Cupid and Psyche shows much elegance combined with graceful proportion.

The Elgin Marbles, now the property of the British nation, belong to a period in the history of Grecian sculpture when the art had reached its highest excellence. " These marbles," we quote from the Library of Useful Knowledge, " chiefly ornamented one edifice, dedicated to the guardian deity of Athens, raised at the time of the greatest political power of the state, when all the arts which contribute to humanize life were developing their beneficial influence. Many of the writers of Athens, whose works are the daily text-books of our schools, saw in their original perfection the mutilated marbles which we cherish and admire. The Elgin collection has presented us with the external and material forms in which the art of Phidias gave life and reality to the beautiful mythi which veiled the origin of his native city, and perpetuated in groups of matchless simplicity the ceremonies of the great national festival. The lover of beauty, and the friend of Grecian learning, will here find a living comment on what he reads; and as in the best and severest models of antiquity we always discover something new to admire, so here we find fresh beauties at every visit, and learn how infinite in variety are simplicity and truth, and how every deviation from these principles produces sameness and satiety."

Materials of Grecian statues.

Clay was the first material employed in statuary. An instance of this may be seen in a figure of Alcamenes in bas-relief in the Villa Albani. The ancients used their fingers, and especially their nails, to render certain parts more delicate and lively; and hence arose the phrase *ad unguem factus homo*, an accomplished man. It was the opinion of Count Caylus, that the ancients did not use models in forming their statues. But to disprove this, it is only necessary to mention an engraving on a stone in the cabinet of Stosch, which represents Prometheus engraving the figure of a man, with a plummet in his hand to measure the proportions of his model. The ancients as well as the moderns made works in plaster; but no specimens remain except some figures in bas-relief, of which the most beautiful were found at Baiæ.

The works made of ivory and silver were generally of a small size. Sometimes, however, statues of a prodigious size were formed of gold and ivory. The colossal Minerva of Phidias, which was composed of these materials, was twenty-six cubits in height.

The Greeks generally hewed their marble statues out of one block, though they afterwards worked the heads separately, and sometimes the arms. The heads of the famous group of Niobe and her Daughters have been adapted to their bodies after being separately finished. It is proved by a large figure representing a river, which is preserved in the Villa Albani, that the ancients first hewed their statues roughly before they attempted to finish any part. When the statue had received its perfect figure, they next proceeded to polish it with pumice-stone, and again carefully retouched every part with the chisel. The ancients, when they employed porphyry, usually made the head and extremities of marble. It is true, that at Venice there are four figures entirely composed of porphyry; but these are the production of the Greeks of the middle age; some of their noblest works were cast in bronze. They also made statues of basalt and alabaster.

III.—ROMAN SCULPTURE.

1.—*Ancient Italian Sculpture.*

The Romans made the conquest of the world so much the passion of their hearts, that they had little enthusiasm to spare for art. They admired the works of Greece, and filled Rome with statues; but though they inherited the empire, they succeeded not to the genius of that little knot of republics. In their hands sculpture soon degenerated; it became more vulgar and more absurd every succeeding reign. As they worshipped the gods of Greece, they were content to find them ready made to their hands, and their chief works were statues of their great men, and triumphal columns and arches. Their best and most characteristic sculpture was history. The Trajan Column represents, in one continued winding relief, from the base to the summit, the actions of the emperor; and his statue stood at the top to show him as the consummation of all glory. The Romans, when they conquered Britain, adorned the temples and courts of justice with statues of divinities. These remains are executed with such deficiency of skill as countenances the conjecture, that the gods and altars, as well as the roads of the time, were executed by the soldiers.

Almost the only excellence to which the Romans could lay claim, was their collection of busts. These, from Julius to Galienus, embracing a period of three centuries, exhibit a series invaluable in the history of art, and in some instances worthy of comparison with the best works of the kind executed in the earlier ages. The busts are confined to the emperors of Rome; all others were forbid to be sculptured. The most perfect specimens cease with the reign of Augustus. Towards the close of the first century, forcible and free execution is substituted for purity of design and natural expression. A stiffness and laboured appearance marks the works of the reign of Hadrian. Some traits of good workmanship are observable in the busts of Aurelius. In the times of Severus the art had degenerated, and every subsequent reign shows a farther debasement, till all traces of excellence finally disappear.

2.—*Modern Italian Sculpture.*

The first revival of modern art may be reckoned from the reign of Constantine, when Christianity was established. We will not, in this sketch, dwell on the works of this period, which indeed do not afford much matter for interesting contemplation; but pass on to the time when indications of real power and genius first appeared. The most distinguished restorer of sculpture was Donatello, born at Florence in 1383. Some of his works, both in bronze and marble, might be placed beside the best productions of ancient Greece without discredit. His alto-relievo of Two Singing Boys is a superior piece of sculpture. The bronze statue of Mercury by this master, at Florence, is equally remarkable. His marble statue of St George was greatly admired by Michel Angelo, who, after gazing at it for some time in silence, suddenly exclaimed "March!" A similar anecdote is told of this great man, who addressed these words to another work of Donatello's, Saint Mark, "Marco, perche non mi parli?" The basso-relievos of the life of Christ by Donatello abound in noble conceptions, but they were the works of advanced age, and were finished by his scholars.

Donatello.

Ghiberti.

Lorenzo Ghiberti, born in 1378, showed his great talents at the early age of twenty-three, when he commenced that splendid work, the doors of the Baptistry at Florence. These doors are three in number, all in bronze. The southern door, on the panels of which are sculptured the life of St John the Baptist, is by Andrea da Pisa. The northern and eastern doors are by Ghiberti. On the former is represented the life of our Saviour, and the latter exhibits the principal events recorded in the Old Testament. They occupied Ghiberti for forty years, and are justly considered noble specimens of art. The eastern door was regarded by Michel Angelo as worthy to be the gate of Paradise.

Michel A gelo Buonarotti.

We come now to notice Michel Angelo, the most illustrious master of modern art, whether regarded as sculptor, painter, or architect. Born in 1474, and living to the advanced age of ninety, this celebrated man was the means of influencing by his mighty genius the efforts of art during the greater part of the sixteenth century. Whatever be the various opinions of Michel Angelo, all unite in acknowledging the wondrous power of his works in sculpture. It is only when he has overstrained the muscular energy of his subjects that fault can be found at all. In some instances we no doubt find him exaggerated, and deficient in repose. His conceptions were generally vast, almost superhuman, and in this spirit they were executed. With him expression and character were primary considerations, and he made ideal beauty and form subservient to his forcible representations. His works have a strong, marked character of their own; his thoughts are always elevated, and his figures full of dignity. He is never feeble. If not sublime, he is never insipid. The sentiment of aggrandizing his subject often prevails. His statue of Moses in S. Pietro, in Vincoli, though severely criticised, is a great work. "The true sublime," says Forsyth, "resists all ridicule. The offended lawgiver frowns on undepressed, and awes you with inherent authority." The recumbent statues in the monument of Julian de' Medicis, in the Medici chapel, of Daybreak and Night, are grand and mysterious, and denote a mighty mind and hand. The pensive sitting figure of Lorenzo de' Medicis is finely conceived; and the Madonna and Child in the same chapel has, in the opinion of Flaxman, "a sentiment of maternal affection never found in Grecian sculpture, but frequently in the works of this artist, particularly in his paintings, and that of the most tender kind." Michel Angelo brought the principles of art to great perfection. "Anatomy," says Flaxman, "the motion and perspective of figure, the complication, grandeur, and harmony of his grouping, with the advantages and facility of execution in painting and sculpture, besides his mathematical and mechanical attainments in architecture and building, which, together with the many and prodigious works he accomplished, demonstrate how greatly he contributed to the restoration of art."

Giovanni Bologna, Cellini, Bernini.

Giovanni di Bologna, a Frenchman by birth, was one of the most celebrated of Michel Angelo's scholars. His Venus coming from the Bath, both standing and kneeling, are remarkable for delicacy and grace; and his Mercury is beautifully conceived and finely executed. Benvenuto Cellini obtained celebrity for his group of Perseus and Medusa. Bernini enjoyed great reputation in his day, but his Apollo and Daphne seems his only work of distinguished merit, although he has been also esteemed for the ease and nature of his portraits. His larger works were considered by Flaxman as remarkable for presuming airs, affected grace, and unmeaning flutter.

Canova.

Sculpture continued to flourish in Italy during a portion of the seventeenth century, but after that it rapidly declined. An illustrious man, however, was destined to raise it to a new existence. Antonio Canova, born in Possagno in 1757, though weakly in constitution, gave early indications of future excellence. His diligence in studying sculpture was unwearied, and he was distinguished among the Venetian artists by a laborious exercise of hand, a restless activity of fancy, and an enthusiastic longing for fame. The people of Venice felt the beauty of Canova's works. He went to Rome and executed his group of Theseus and the Minotaur, which was pronounced by the first judges as "one of the most perfect works which Rome had beheld for ages." From this fortunate hour to the end of his life, he produced a rapid succession of statues and groups, which carried his fame far and wide over the world. Before 1800 he had given to the world some of his most successful performances; the monuments of Ganganelli and Rezzonico; the groups of Venus and Adonis, and of Cupid and Psyche; the Hebe, and the Sommariva Magdalene. These statues were entirely by his own hands, unassisted by workmen. When his success produced wealth, his protection of rising merit was admirable. His liberality in this respect was as boundless as his enthusiasm for the arts. He died in 1822, having executed fifty-three statues, twelve groups, and monuments, busts, and relievos amounting to the extraordinary number of 176 complete works, which are now dispersed all over Europe. Canova principally excelled in the beautiful and graceful. He never attempted to tread

Di Michel Angeol la terribil via.

Hence his favourite subjects were those of female grace or youthful beauty. Paris, Perseus, Palamedes, Psyche, Hebe, Venus, Nymphs, and Dancers, are the most popular of all his works. In some of these there is an approach to affectation and French taste, especially in the draperies; and, perhaps, in avoiding the extremes of anatomical force and muscular development, he has too much addicted himself to flowing outline and polished surface. But his taste improved with his progress in the art. He felt the superiority of simplicity over affectation, as is visibly shown in the noble productions of his riper years, his Pauline, the mother of Buonaparte, the Endymion, and the recumbent Magdalene. Although his power of conception was inferior to the illustrious artists of Greece, he nevertheless rivalled them in the vivid grace and exquisite skill of his works. Well did Byron say, in the lifetime of this great artist,

Such as the great of yore, Canova is to-day.

Living artists of the Italian school.

The genius of Canova gave a new impulse to Italian sculpture. Thorwaldsen, though a Dane by birth, may be considered an Italian artist. His Triumph of Alexander, the Mercury, the Night, and Aurora, are works which have sufficiently established the claim of this great artist to the admiration of his own age, and that of posterity. Danneker, the sculptor of the Ariadne at Francfort, seems also to belong to the existing school of Italy. There are others, whom we cannot enumerate, who are also in the fair road to eminence; but, singular to say, few of these are sons of that land which has so well been called

Mother of arts, as once of arms.

IV.—ENGLISH SCULPTURE.

The Romans, when they withdrew their troops from Britain, left some taste for sulpture behind them, and their successors the Saxons made attempts to imitate the human form. The Normans introduced a better style of art, and the return of the crusaders brought a relish for Grecian statuary into this country. In the reign of Henry III. the works of English artists were characterized by good sense and simple grace, which redeemed the imperfections of workmanship. In the chapel of Henry VII. we see monuments carved with great skill. The Protestant religion was not favourable to the art, and our sculptures, after the Reformation, were mostly by foreigners. The first English sculptor of note was Gibbons, who, about the close of the seventeenth century, executed many admirable works in wood. About the same time lived Cibber, an artist of originality and power. The far-famed figures of Raving and Melancholy, carved in stone, are his best-known productions, and, in spite of Pope's satirical lines on the "brainless brothers," they stand foremost in conception and second in execution among the efforts of English sculpture. The bas-reliefs on the sides of the monument in London, and some statues at Chatsworth, are from his chisel.

Gibbons, Cibber.

Roubiliac.

Roubiliac, a Frenchman by birth, was so long resident in England that he has been adopted as a British artist. Although Flaxman has pronounced a poor opinion of Roubiliac's works, they have nevertheless taken a lasting hold of public admiration. He was a man deeply imbued with poetic feelings, and had an unbounded enthusiasm for his profession. Some of his works are fanciful and conceited, but others again possess much elegance of action, and all are very beautifully executed. His figure of Eloquence is masterly and graceful. Canova said it was one of the noblest statues he had seen in England. The statue of Sir Isaac Newton is another of his masterpieces; Chantrey calls it "the noblest of all our English statues. There is an air of nature and a loftiness of thought about it, which no other artist has in this country, I suspect, reached. You cannot imagine any thing grander in sentiment, and the execution is every way worthy of it." His most famous work is the monument of Mrs Nightingale, in Westminster Abbey: with some allegorical extravagance, it exhibits feeling and pathos, and the workmanship is quite marvellous.

Banks.

"Banks," says Cunningham, "was the first of our native sculptors whose aims were uniformly lofty and heroic, and who desired to bring poetry to the aid of all his compositions." His groups and statues were, however, coldly received. His sketches, which are full of vigour and feeling, have been highly esteemed. The statue of Achilles mourning the loss of Briseis has not been excelled for fine action and noble proportions. Nollekens, like Banks, was ambitious to introduce a purer and more tasteful style of art, but his great works hardly came up to expectation. His busts are however excellent, and will preserve his fame. Cunningham, from whose agreeable publication on English art we have already quoted, says, "the claims of Nollekens to distinction are threefold; bust sculpture, monumental sculpture, and poetic sculpture. He attained to eminence in all, but to lasting fame, I apprehend, only in the first, and even then the permanent meed is secured to him more from the lasting importance of some of his subjects, than from the splendour of the art with which he has invested them." Bacon infused more English sense into sculpture than any of his predecessors, or his contemporaries Banks and Nollekens. His statue of Samuel Johnson, in St Paul's, is an excellent work; stern, severe, full of surly thought and conscious power. Howard, also in St Paul's, is expressive of the philanthropic and benevolent man it represents. Bacon had great skill in workmanship, and he never spared his labour. Some of his monuments are rather too much crowded with ornaments and objects of secondary interest.

Nollekens.

Bacon.

Flaxman.

The most eminent sculptor this country has yet produced, John Flaxman, was born in 1755. "The elements of his style," said Sir Thomas Lawrence, "were founded in Grecian art—on its noblest principles—on its deeper intellectual power, and not on the mere surface of its skill. Though master of its purest lines, he was still more the sculptor of sentiment than of form; and whilst the philosopher, the statesman, and the hero, were treated by him with appropriate dignity, not even in Raphael have the gentler feelings and sorrows of human nature been treated with more touching pathos than in the various degrees and models of this inestimable man. Like the greatest of modern painters, he delighted to trace, from the actions of familiar life, the lines of sentiment and passion, and, from the populous haunts and momentary peacefulness of poverty and want, to form his inestimable groups of childhood and maternal tenderness, with those nobler compositions from holy writ, as beneficent in their motive as they were novel in design." The classical productions of Flaxman are now known far and wide, and they have given the world a high idea of the genius of England. "Michel Angelo and Flaxman," observes an excellent critic, "are the only two sculptors who, with genius for the minute as well as the grand, have dared sometimes to be remiss, and leave sentiment to make its way without the accompanying graces of skilful labour." His workmanship was certainly sometimes slovenly, and his draperies heavy. The monuments he executed are not his ablest works. His illustrations of Homer, Æschylus, and Dante, are worthy of the great originals; and the engravings from these works have given Flaxman an European reputation. The mind of this great artist was essentially poetical, and his genius was, in the strictest sense of the words, original and inventive.

We must touch lightly on the living artists of this country. It is satisfactory to think that ours is not an age in which sculpture is retrograding in Britain. The splendid genius of Chantrey has nobly sustained the reputation Flaxman earned for us. His statues, now very numerous, are works of decided excellence; whilst his busts are the most admirable productions of that kind in the world. Westmacott has also shared largely in public favour. Several of his monuments and other works are ably executed. We do not name other artists of rising fame. Their merit, if they truly possess any, will be duly appreciated, for a correct taste in works of sculpture is every day becoming more generally diffused in Britain.

V.—FRENCH, SPANISH, AND GERMAN SCULPTURE.

French sculpture.

Our sketch would be imperfect did we not allude to the sculpture of France, Spain, and Germany. In France, the art began to be practised with success about the middle of the sixteenth century. Gougon finished the famous Fountain of the Innocents in 1550. The works of Cousin evince genius; and Pilon has been admired for energy in his productions. Jacques D'Angouleme, a contemporary of Michel Angelo's, possesses merit. Giovanni di Bologna, of whom we have previously spoken, filled his country with the principles of his master. Sculpture flourished in France during the reign of Louis XIV. Voltaire says of one of the artists of this time, Girandon, "il a égalé tout ce que l'antiquité a de plus beau." This is great praise, and scarcely merited, although his designs are noble and his taste correct. An example of his style is well seen in his Tomb of Richelieu. Puget is also much esteemed by his countrymen. The succeeding artists of France were followers more or less of the styles of Girandon and Puget. The art may be said to be in a flourishing state at present.

Spanish sculpture.

A great number of names have been recorded by Spanish writers as eminent in sculpture. The greater part of them seem to have been employed in ornamenting the churches of Spain, and few are known from their works in other countries. Berruguete, one of the best artists of Spain, studied under Michel Angelo at Rome, and adorned Madrid, Saragossa, and other towns, with his works, which exhibit much of the grandeur and expression of ancient art. After him Paul de Cespedes was celebrated as a sculptor of great skill. In the eighteenth century Philip de Castro became a distinguished sculptor, and contributed greatly to spread the principles of correct taste in Spain.

German sculpture.

Prior to the seventeenth century, Germany appears to have made little progress in sculpture. Ranchmuller preceded Schluter of Hamburg, who repaired to Rome, and attached himself to the manner of Michel Angelo. Messerschmidt executed many excellent pieces of sculpture in Vienna. In later times Ohnmacht, Sonnenschein, Nahl, and the two Shadofs, have distinguished themselves as artists. The Spinning Girl of the Younger Shadof is an exquisite piece of sculpture. The Germans promise to advance rapidly in sculpture, from the enthusiasm they show in acquiring the true principles of the art.

VI.—OF EXPRESSION, ACTION, AND PROPORTION IN SCULPTURE.

Expression and attitude.

Without expression, gesture, and attitude, no figure can be beautiful, because in these the graces always reside. It was for this reason that the graces are always represented as the companions of Venus.

The expression of tranquillity was frequent in Grecian statues, because, according to Plato, that was considered as the middle state of the soul between pleasure and pain. Experience, too, shows that in general the most beautiful persons are endowed with the sweetest and most engaging manner. Without a sedate tranquillity, dignified beauty could not exist. It is in this tranquillity, therefore, that we look for the complete display of genius.

The most elevated species of tranquillity and repose was studied in the figures of the gods. The father of the gods, and even inferior divinities, are represented without emotion or resentment. It is thus that Homer paints Jupiter shaking Olympus by the motion of his hair and his eyebrows. Jupiter, however, is not always exhibited in this tranquil state. In a bas-relief belonging to Rondini he appears seated on an arm-chair with a melancholy aspect. The Apollo of the Vatican represents the god in a fit of rage against the serpent Python, which he kills at a blow. The artist, adopting the opinion of the poets, has made the nose the seat of anger, and the lips the seat of disdain.

To express the action of a hero, the Grecian sculptors delineated the countenance of a noble virtuous character repressing his groans, and allowing no expression of pain to appear. In describing the actions of a hero, the poet has much more liberty than the artist. The poet can paint them such as they were before men were taught to subdue their passions by the restraints of law or the refined customs of social life. But the artist, obliged to select the most beautiful forms, is reduced to the necessity of giving such an expression of the passions as may not shock our feelings and disgust us with his production. The truth of these remarks will be acknowledged by those who have seen two of the most beautiful monuments of antiquity, one of which represents the fear of death, the other the most violent pains and sufferings. The daughters of Niobe, against whom Diana has discharged her fatal arrows, are exhibited in that state of stupefaction which we imagine must take place when the certain prospect of death deprives the soul of all sensibility. The fable presents us an image of that stupor which Æschylus describes as seizing the daughters of Niobe when they were transformed into a rock. The other monument referred to is the image of Laocoon, which exhibits the most agonizing pain that can affect the muscles, the nerves, and the veins. The sufferings of the body and the elevation of the soul are expressed in every member with equal energy, and form the most sublime contrast imaginable. Laocoon appears to suffer with such fortitude, that, whilst his lamentable situation pierces the heart, the whole figure fills us with an ambitious desire of imitating his constancy and magnanimity in the pains and sufferings that may fall to our lot.

Philoctetes is introduced by the poets as shedding tears, uttering complaints, and rending the air with his groans and cries; but the artist exhibits him silent, and bearing his pains with dignity. The Ajax of Timomachus is not drawn in the act of destroying the sheep which he took for the Grecian chiefs, but in the moments of reflection which succeeded those of frenzy. So far did the Greeks carry their love of calmness and slow movements, that they thought a quick step always announced rusticity of manners. Demosthenes reproaches Nicobulus for this very thing; and from the words he makes use of, it appears that to speak with insolence and to walk hastily were reckoned synonymous.

In the figures of women the artists have conformed to the principle observed in all the ancient tragedies, and recommended by Aristotle, never to make women show too much intrepidity or excessive cruelty. Conformably to this maxim, Clytemnestra is represented at a little distance from the fatal spot, watching the murderer, but without taking any part with him. In a painting of Timomachus representing Medea and her children, when Medea lifts up the dagger they smile in her face, and her fury is immediately melted into compassion for the innocent victims. In another representation of the same subject Medea appears hesitating and indecisive. Guided by the same maxims, the artists of most refined taste were careful to avoid all deformity, choosing rather to recede from truth than from their accustomed respect for beauty, as may be seen in several figures of Hecuba. Sometimes, however, she appears in the decrepitude of age, her face furrowed with wrinkles, and her breasts hanging down.

Illustrious men, and those invested with the offices of dignity, are represented with a noble assurance and a firm aspect. The statues of the Roman emperors resemble those of heroes, and are far removed from every species of flattery, in the gesture, in the attitude, and in the action. They never appear with haughty looks, or with the splendour of royalty; no figure is ever seen presenting any thing to them with bended knee except captives, and none addresses them with an inclination of the head. In modern works too little attention has been paid to the ancient costume. Winckelman mentions a bas-relief which was executed at Rome for the fountain of Trevi, representing an architect in the act of presenting the plan of an aqueduct to Marcus Agrippa. The modern sculptor, not content with giving a long beard to that illustrious Roman, contrary to all the ancient marble statues as well as medals which remain, exhibits the architect on his knees.

In general it was an established principle to banish all violent passions from public monuments. This will serve as a decisive mark to distinguish the true antique from supposititious works. A medal has been found exhibiting two Assyrians, a man and woman, tearing their hair; with this inscription, ASSYRIA. ET. PALAESTINA. IN. POTEST. P. R. REDAC. S. C. The forgery of this medal is manifest from the word *Palaestina*, which is not to be found in any ancient Roman medal with a Latin inscription. Besides, the violent action of tearing the hair does not suit any symbolical figure. This extravagant style has been imitated by some of the modern artists. Their figures resemble comedians on the ancient theatres, who, in order to suit the distant spectators, put on painted masks, employed exaggerated gestures, and far overstepped the bounds of nature. This style has been reduced into a theory in a treatise on the passions, composed by Le Brun. The designs which accompany that work exhibit the passions in the very highest degree, approaching even to frenzy. But these are calculated to vitiate the taste, especially of the young; for the ardour of youth prompts them rather to seize the extremity than the middle; and it will be difficult for that artist who has formed his taste from such impassioned models ever to acquire that noble simplicity and sedate grandeur which distinguished the works of ancient taste.

Of proportion.

Proportion is the basis of beauty; indeed there can be no beauty without it, but proportion may exist where there is little beauty. Experience every day teaches us that knowledge is distinct from taste; and proportion, therefore, which is founded on knowledge, may be strictly observed in any figure, and yet the figure have no pretensions to beauty. The ancients considering ideal beauty as the most perfect, have frequently employed it in preference to the beauty of nature.

The body consists of three parts, as well as the members. The three parts of the body are the trunk, the thighs, and the legs. The inferior parts of the body are the thighs, the legs, and the feet. The arms also consist of three parts, and these three parts must bear a certain proportion to the whole as well as to one another. In a well-formed man the head and body must be proportioned to the thighs, the legs, and the feet, in the same manner as the thighs are proportioned to the legs and the feet, or the arms to the hands. The face also consists of three parts, that is, three times the length of the nose; but the head is not four times the length of the nose, as some writers have asserted. From the place where the hair begins to the crown of the head are only three fourths of the length of the nose, or that part is to the nose as nine to twelve.

It is probable that the Grecian as well as Egyptian artists have determined the great and small proportions by fixed rules, and established a positive measure for the dimensions of length, breadth, and circumference. This supposition alone can enable us to account for the great conformity which we meet with in ancient statues. Winckelman thinks that the foot was the measure which the ancients used in all their great dimensions, and that it was by the length of it that they regulated the measure of their figures, by giving to them six times that length. This, in fact, is the length which Vitruvius assigns (*Pes vero altitudinis corporis sextæ*, lib. iii. cap. 1). That celebrated antiquary thinks the foot is a more determinate measure than the head or the face, the parts from which modern painters and sculptors often take their proportions. This proportion of the foot to the body, which has appeared strange and incomprehensible to the learned Huet, and has been entirely rejected by Perrault, is however founded upon experience. After measuring with great care a vast number of figures, Winckelman found this proportion observed not only in Egyptian statues, but also in those of Greece. This fact may be determined by an inspection of those statues the feet of which are perfect. One may be fully convinced of it by examining some divine figures, in which the artists have made some parts beyond their natural dimensions. In the Apollo Belvidere, which is a little more than seven heads high, the foot is three Roman inches longer than the head. The head of the Venus de' Medicis is very small, and the height of the statue is seven heads and a half; the foot is three inches and a half longer than the head, or precisely the sixth part of the length of the whole statue.

VII.—PRACTICE OF SCULPTURE.

Grecian sculpture studied by modern artists.

We have been thus minute in our account of the Grecian sculpture, because it is the opinion of the ablest critics that modern artists have been more or less eminent as they have studied with the greater or less attention the models left us by that ingenious people. Winckelman goes so far as to contend that the most finished works of the Grecian masters ought to be studied in preference even to the works of nature. This appears to be paradoxical; but the reason assigned for his opinion is, that the fairest lines of beauty are more easily discovered, and make a more striking and powerful impression, by their reunion in these sublime copies, than when they are scattered far and wide in the original. Allowing, therefore, the study of nature the high degree of merit it so justly claims, it must nevertheless be granted that it leads to true beauty by a much more tedious, laborious, and difficult path, than the study of the antique, which presents immediately to the artist's view the object of his researches, and combines, in a clear and strong point of light, the various rays of beauty that are dispersed throughout the wide domain of nature.

As soon as the artist has laid this excellent foundation, acquired an intimate degree of familiarity with the beauties of the Grecian statues, and formed his taste after the admirable models they exhibit, he may then proceed with advantage and assurance to the imitation of nature. The ideas he has already formed of the perfection of nature, by observing her dispersed beauties combined and collected in the compositions of the ancient artists, will enable him to acquire with facility, and to employ with advantage, the detached and partial ideas of beauty which will be exhibited to his view in a survey of nature in her actual state. When he discovers these partial beauties, he will be capable of combining them with those perfect forms of beauty with which he is already acquainted. In a word, by having always present to his mind the noble models already mentioned, he will be in some measure his own oracle, and will draw rules from his own mind.

Two ways of imitating nature.

There are, however, two ways of imitating nature. In the one a single object occupies the artist, who endeavours to represent it with precision and truth; in the other, certain lines and features are taken from a variety of objects, and combined and blended into one regular whole. All kinds of copies belong to the first kind of imitation; and productions of this kind must be executed necessarily in the Dutch manner, that is to say, with high finishing, and little or no invention. But the second kind of imitation leads directly to the investigation and discovery of true beauty, of that beauty whose idea is connate with the human mind, and is only to be found there in its highest perfection. This is the kind of imitation in which the Greeks excelled, and in which men of genius excite the young artists to excel after their example, namely, by studying nature as they did. After having studied in the productions of the Grecian masters their choice and expression of select nature, their sublime and graceful contours, their noble draperies, together with that sedate grandeur and admirable simplicity that constitute their chief merit, the curious artists will do well to attend to the manual and mechanical part of their operations, as this is absolutely necessary to the successful imitation of their excellent manner.

Models of statues.

It is certain that the ancients almost always formed their first models in wax. To this modern artists have substituted clay, or some such composition. They prefer clay before wax in the carnations, on account of the yielding nature of the latter, and its sticking in some measure to every thing it touches. We must not, however, imagine from hence that the method of forming models of wet clay was either unknown or neglected among the Greeks. On the contrary, it was in Greece that models of this kind were invented. Their author was Dibutades of Sicyon; and it is well known that Arcesilas, the friend of Luculkus, obtained a higher degree of reputation by his clay models than by all his other productions. Indeed if clay could be made to preserve its original moisture, it would undoubtedly be the fittest substance for the models of the sculptor; but when it is placed either in the fire or left to dry imperceptibly in the air, its solid parts grow more compact, and the figure, losing thus a part of its dimensions, is necessarily reduced to a smaller volume. This diminution would be of no consequence did it equally affect the whole figure, so as to preserve its proportions entire. But this is not the case. For the smaller parts of the figure dry sooner than the larger; and thus losing more of their dimensions in the space of time than the latter do, the symmetry and proportions of the figure inevitably suffer. This inconvenience does not take place in those models that are made in wax. It is indeed extremely difficult, in the ordinary method of working the wax, to give it that degree of smoothness that is necessary to represent the softness of the carnations or fleshy parts of the body. This inconvenience may, however, be remedied by forming the model first in clay, then moulding it in plaster, and lastly casting it in wax. And, indeed, clay is seldom used but as a mould in which to cast a figure of plaster, stucco, or wax, to serve henceforth for a model by which the measures and proportions of the statue are to be adjusted. In making waxen models, it is common to put half a pound of colophony to a pound of wax; and some add turpentine, melting the whole with oil of olives.

Method of working the marble.

So much for the first or preparatory steps in this procedure. It remains to consider the manner of working the marble after the model so prepared. The method here followed by the Greeks seems to have been extremely different from that which is generally observed by modern artists. In the ancient statues we find the most striking proofs of the freedom and boldness that accompanied each stroke of the chisel, and which resulted from the artist's being perfectly sure of the accuracy of his idea, and the precision and steadiness of his hand. The most minute parts of the figure carry these marks of assurance and freedom; no indication of timorousness or diffidence appears, nothing that can induce us to fancy that the artist had occasion to correct any of his strokes. It is difficult to find, even in the second-rate productions of the Grecian artists, any mark of a false stroke or a random touch. This firmness and precision of the Grecian chisel was certainly derived from a more determined and perfect set of rules than those which are observed in modern times.

The method generally observed by the modern sculptor is as follows. First, out of a great block of marble he saws another of the size required, which is performed with a steel saw without teeth, casting water and sand thereon from time to time; then he fashions it, by taking off what is superfluous with a steel point and a heavy hammer of soft iron; after this, bringing it near the measure required, he reduces it still nearer with another finer point; he then uses a flat cutting instrument, having notches in its edge, and a chisel to take off the scratches which the former has left; till at length, taking rasps of different degrees of fineness, he by degrees brings his work into a condition for polishing.

After this, having studied his model with all possible attention, he draws upon this model horizontal and perpendicular lines which intersect each other at right angles. He afterwards copies these lines upon his marble, as the painter makes use of such transverse lines to copy a picture, or to reduce it to a smaller size. These transverse lines or squares, drawn in an equal number upon the marble and upon the model, in a manner proportioned to their respective dimensions, exhibit accurate measures of the surfaces upon which the artist is to work; but cannot determine, with equal precision, the depths that are proportioned to these surfaces. The sculptor, indeed, may determine these depths by observing the relation they bear to his model; but as his eye is the only guide he has to follow in this estimate, he is always more or less exposed to error, or at least to doubt. He is never sure that the cavities made by his chisel are exact; a degree of uncertainty accompanies each stroke; nor can he be assured that it has carried away neither too much nor too little of his marble. It is equally difficult to determine, by such lines as have already been mentioned, the external and internal contours of the figure, or to transfer them from the model to the marble. By the internal contour is understood that which is described by the parts which approach towards the centre, and which are not marked in a striking manner.

It is further to be noticed, that in a complicated and laborious work, which an artist cannot execute without assistance, he is often obliged to make use of foreign hands, which have not the talents nor the dexterity that are necessary to finish his plan. A single stroke of the chisel that goes too deep is a defect not to be repaired; and such a stroke may easily happen, where the depths are so imperfectly determined. Defects of this kind are inevitable, if the sculptor, in chipping his marble, begins by forming the depths that are requisite in the figure which he designs to represent. Nothing is more liable to error than this manner of proceeding. The cautious artist ought, on the contrary, to form these depths gradually, by little and little, with the utmost circumspection and care; and the determining of them with precision ought to be considered as the last part of his work, and the finishing touches of his chisel.

Method of copying ancient statues.

The various inconveniences attending this method determined several eminent artists to look out for one that would be liable to less uncertainty, and productive of fewer errors. The French Academy of Painting at Rome devised a method of copying the ancient statues, which some sculptors have employed with success, even in the figures which they finished after models in clay or in wax. This method is as follows. The statue that is to be copied is enclosed in a frame that fits it exactly. The upper part of this frame is divided into a certain number of equal parts, and to each of these parts a thread is fixed with a piece of lead at the end of it. These threads, which hang freely, show what parts of the statue are most removed from the centre with much more perspicuity and precision than the lines which are drawn on its surface, and which pass equally over the higher and hollow parts of the block. They also give the artist a tolerable rule to measure the more striking variations of height and depth, and thus render him more bold and determined in the execution of his plan.

But even this method is not without its defects. For as it is impossible, by means of a straight line, to determine with precision the procedure of a curve, the artist has, in this method, no certain rule to guide him in his contours; and as often as the line which he is to describe deviates from the direction of plumb-line, which is his main guide, he must necessarily feel himself at a loss, and be obliged to have recourse to conjecture. It is also evident, that this method affords no certain rule to determine exactly the proportion which the various parts of the figure ought to bear to each other, considered in their mutual relation and connections. The artist, indeed, endeavours to supply this defect by intersecting the plumb-lines by horizontal ones. This resource has, nevertheless, its inconveniences, since the squares formed by transverse lines that are at a distance from the figure, although they be exactly equal, yet represent the parts of the figure as greater or smaller, according as they are more or less removed from our position or point of view. But notwithstanding these inconveniences, the method now under consideration is certainly the best that has hitherto been employed. It is surer and more practicable than any other we know, although it appears, from the remarks we have now been making, that it does not exhibit a sure and universal criterion to a sculptor who executes after a model.

Of polishing statues.

To polish the statue, or make the parts of it smooth and sleek, pumice-stone and smelt are used; then tripoli; and when a still greater lustre is required, burned straw is employed.

SCUPPERS are pipes of lead inserted in openings bored from the deck through the sides of a ship, to carry the water off from the deck to the sea. To avoid the inconvenience of having the scuppers broken by the working of the ship, each is formed of two pipes, one of which is passed upwards to the deck through the opening in the ship's side, and having its lower end nailed on the outside planking; the other, which is of smaller diameter, after being woolded on the outside with flannel dipped in tallow, is passed downwards into the lower pipe, through the opening in the deck, and its upper end secured on the plank of the deck. In order to prevent the entrance of water by these scuppers when a ship is inclined, valves of metal are placed over the external outer ends, which close with the pressure of the external water. In merchant-vessels, leather-pipes, called scupper-hoses, are sometimes nailed round the opening for the same purpose. Sometimes scuppers are only leaden pipes passed through the ship's side, and turned and fastened at each end.

SCURVY, a dreadful disease, in the prevention and cure of which, Dr Beddoes thinks, the mineral acids, especially the nitric and vitriolic, may be employed with as much success as the vegetable acids.

SCUTAGE (*scutagium;* Saxon, *scildpening*) was a tax or contribution raised by those that held lands by knights' service, towards furnishing the king's army, at one, two, or three merks for every knight's fee. Henry III., for his voyage to the Holy Land, had a tenth granted by the clergy, and scutage, three merks of every knight's fee, by the laity. This was also levied by Henry II., Richard I., and King John.

SCUTARI, a city of the western part of Turkey, the capital of the province of the same name, sometimes also called by the Turks Iskandria. It is situated on the river Drenas, at its efflux from the Lake Bojana. It is the seat of a Greek bishop. It contains Greek and Catholic churches, several mosques, and about 4000 houses, with 16,000 inhabitants. There is a considerable employment furnished by the building of ships and exporting of timber, and by fisheries. It is not on the sea-shore; but the village of Polna is the place where vessels load and unload, and which is fortified and protected by the castles Dragos and Golbaschi.

SCUTE (*scutum*), a French gold coin of three shillings and fourpence in the reign of Henry V. Catharine queen of England had an assurance made her of sundry castles, manors, lands, &c. valued at the sum of forty thousand scutes, two of which were worth a noble.

SCUTTLES, in a ship, holes in the decks of a ship, either for air, or as passages to the store-rooms; also openings in a ship's side for the admission of air. If, in order to sink a ship, a hole be cut in her bottom, she is said, in nautical language, to be scuttled.

SCYLAX, a celebrated mathematician and geographer of Caria, flourished under the reign of Darius Hystaspes, about 558 before Christ. Some have attributed to him the invention of geographical tables. We have under his name a geographical work published by Hœschelius; but it is written by a much later author, and is perhaps only an abridgment of Scylax's Ancient Geography.

SCYLLA, in *Ancient Geography*, a rock in the *Fretum Siculum*, near the coast of Italy, dangerous to shipping, opposite to Charybdis, a whirlpool on the coast of Sicily, and both of them famous in mythology. Scylla and Charybdis have been almost subdued by the repeated convulsions of this part of the earth, and by the violence of the current, which is continually increasing the breadth of the straits. If proper allowance be made for these circumstances, we shall acquit the ancients of exaggeration, notwithstanding the dreadful colours in which they have painted this passage. It is formed by a low peninsula called Cape Pelorus, stretching eastward on the Sicilian side, immediately within which lies the whirlpool of Charybdis; and by the rocks of Scylla, which a few miles below, on the Calabrian shore, project westward. The current runs with surprising force from the one to the other alternately in the direction of the tide, and the tides themselves are very irregular. Thus vessels, by shunning the one, were in the utmost danger of being swallowed up by the other.

At present, in moderate weather, when the tide is either at ebb or flood, boats pass across the whirlpool; but, in general, it is like the meeting of two contending currents, with a number of eddies all around; and even now, there is scarcely a winter in which there are not some wrecks.

SCYROS, an island in the Ægean Sea, at the distance of about twenty-eight miles north-east from Eubœa. It is sixty miles in circumference. It was originally in the possession of the Pelasgians and Carians. Achilles retired there to avoid going to the Trojan war, and became father of Neoptolemus, by Deidamia, the daughter of King Lycomedes. Scyros, which was conquered by the Athenians under Cimon, was very rocky and barren. It is now called Sciro. Long. 25. 0. E. Lat. 38. 15. N.

SCYTALA Laconica, in *Antiquity*, a stratagem or device of the Lacedæmonians, for the secret writing of letters to their correspondents, so that if they should chance to be intercepted, nobody might be able to read them.

To this end they had two wooden rollers or cylinders, perfectly alike and equal; one of which was kept in the city, the other by the person to whom the letter was directed. For the letter, a skin of very thin parchment was wrapped round the roller, on which the matter was written; and this being done, it was taken off, and sent away to the party, who, upon putting it in the same manner upon his roller, found the lines and words in the very same disposition as when they were first written.

SCYTHE, a well-known instrument, which has been long employed in cutting grass. See Agriculture.

SCYTHIA, an ancient name for the northern parts of Asia, now known by the name of Tartary; and also for some of the north-eastern parts of Europe.

This vast territory, which extends itself from the Ister or Danube, the boundary of the Celts, that is, from about the 25th to almost the 110th degree of east longitude, was divided into Scythia in Europe and Scythia in Asia, including, however, the two Sarmatias, or, as they are called by the Greeks, Sauromatias, now Circassian Tartary, which lay between and separated the two Scythias from each other. Sauromatia was also distinguished into European and Asiatic; and was divided from the European Scythia by the river Don or Tanais, which falls into the Palus Mæotis, and from the Asiatic by the Rha or Volga, which empties itself into the Caspian Sea.

The Asiatic Scythia comprehended, in general, Great Tartary, and Russia in Asia; and, in particular, the Scythia beyond or without Imaus contained the regions of Bogdoi or Ostiacoi, and Tanguti. That within or on this side of Imaus had Turkestan and Mongul, the Usbeck or Zagatai, Kalmuck and Nagaian Tartars, besides Siberia, the land of the Samoiedes, and Nova Zembla. These three last not being so soon inhabited as the others, were, as may be reasonably supposed, wholly unknown to the ancients; and the former were peopled by the Bactrians, Sogdians, Gandari, Sacks, and Massagetes. As for Sarmatia, it contained Albania, Iberia, and Colchis, which now form Circassian Tartary and the province of Georgia.

Scythia in Europe reached, towards the south-west, to the Po and the Alps, by which it was divided from Celto-Gallia. It was bounded on the south by the Ister or Danube and the Euxine Sea. Its northern limits have been supposed to stretch to the fountain-heads of the Borysthenes or Dnieper, and the Volga, and so to that of the Tanais. The ancients divided this country into Scythia Arimaspæa, which lay eastward, joining to Scythia in Asia; and Sarmatia Europeana on the west. In Scythia properly so called were the Arimaspæi on the north, the Getæ or Dacians along the Danube on the south, and the Neuri between these two. It contained therefore European Russia or Muscovy, and the Lesser Crim Tartary, to the eastward; and, on the west, Lithuania, Poland, part of Hungary, Transylvania, Walachia, Bulgaria, and Moldavia. Sarmatia is supposed to have reached northward to that part of Sweden called *Feningia*, now Finland; in which they placed the Oœnes, Panoti, and Hippopodes. This part they divided from Northern Germany, now the western part of Sweden and Norway, by the *Mare Sarmaticum* or *Scythicum*, which they supposed to run up into the Northern Ocean, and, dividing Lapland into two parts, formed the western part of Sweden and Norway into one island, and Finland into another; supposing this also to be cut off from the continent by the gulf of the same name.

Although the ancient Scythians were celebrated as a warlike people, yet their history is too uncertain and obscure to enable us to give any detail which would not prove equally tiresome and uninteresting to the reader. Mr Pinkerton, in a dissertation on their origin, endeavours to prove that they were the most ancient of nations; and he assigns for the place of their first habitation the country known by the name of Persia. From Persia, he thinks, they proceeded in numerous hordes westward, surrounded the Euxine, and peopled Germany, Italy, Gaul, the countries bordering on the Baltic, and part of Britain and Ireland. That the Scythians were of Asiatic origin, cannot, we think, be questioned; and as Persia was peopled at a very early period, it may not improbably have been their parent country. But when our author contends that their empire had subsisted for more than 1500 years before Ninus, the founder of the Assyrian monarchy, and that it extended from Egypt to the Ganges, and from the Persian Gulf and Indian Sea to the Caspian, we cannot help thinking that his prejudices against the Celts, and his desire to do honour to his favourite Goths, have made him advance a paradox inconsistent with the most authentic records of antiquity. His dissertation however is ingenious, and replete with curious learning.

SEA, in a strict sense, signifies a large portion of water almost surrounded by land, as the Baltic and Mediterranean Seas; but it is frequently used for that vast body of water which encompasses the whole earth. See the articles Geology and Physical Geography.

Sea-Air is that part of the atmosphere which is above the sea. Sea-air has been found salubrious and beneficial in certain distempers. This may be owing to its containing a greater portion of oxygenous gas or vital air, and being less impregnated with noxious vapours, than the land. Dr Ingenhousz made several experiments to ascertain the salubrity of sea-air. By mixing equal measures of common air and nitrous air, he found that at Gravesend they occupied about 1·04, or one measure and $\frac{4}{100}$ths of a measure; whereas on sea, about three miles from the mouth of the Thames, two measures of air, one of common and one of nitrous air, occupied from 0·91 to 0·94. He attempted a similar experiment on the middle of the channel between the English coast and Ostend; but the motion of the ship rendered it impracticable. He found that in rainy and windy weather the sea-air contained a smaller quantity of vital air than when the weather was calm. On the sea-shore at Ostend it occupied from 94½ to 97; at Bruges he found it at 105, and at Antwerp 109½. Dr Ingenhousz thus concludes his paper. "It appears, from these experiments, that the air at sea and close to it is in general purer and fitter for animal life than the air on the land, though it seems to be subject to the same inconstancy in its degree of purity with that of the land; so that we may now with more confidence send our patients labouring under consumptive disorders to the sea, or at least to places situated close to the sea, which have no marshes in their neighbourhood. It seems also probable that the air will in general be found much purer far from the land than near the shore, the former being never subject to be mixed with land-air."

SEA-LIGHTS.

SEA-LIGHT, and Lighthouse, are terms which, although not strictly synonymous, are indifferently employed to denote the same thing. A *Sea-light* may be defined as *a light so modified and directed as to present to the mariner an appearance which shall at once enable him to judge of his position during the night, in the same manner as the sight of a landmark would do during the day.*

Early history.

The early history of lighthouses is very uncertain; and many ingenious antiquaries, finding the want of authentic records, have endeavoured to supply the deficiency by conjectures based upon casual and obscure allusions in ancient writers, and have invented many vague and unsatisfactory hypotheses on the subject, drawn from the heathen mythology. Some writers have gone so far as to imagine, that the Cylcopes were the keepers of lighthouses; whilst others have actually maintained that Cyclops was intended, by a bold prosopopœia, to represent a lighthouse itself. A notion so fanciful deserves little consideration; and in order to show how ill it accords with that mythology of which it is intended to be an exposition, it seems enough to quote the lines from the ninth Odyssey, where Homer, after describing the darkness of the night, informs us that the fleet of Ulysses actually struck the shore of the Cyclopean island, before it could be seen.

> Ἔνθ᾽ ὄυτις τὴν νῆσον ἐσέδρακεν ὀφθαλμοῖσιν
> Ὄυτ᾽ οὖν κύματα μακρὰ κυλινδόμενα ποτὶ χέρσον
> Ἐισίδομεν πρὶν νῆας ἐϋσσέλμους ἐπικελσαι
>
> *Odyss.* ix. 146.

There does not appear any better reason for supposing, that under the history of Tithonus, Chiron, or any other personage of antiquity, the idea of a lighthouse was conveyed; for such suppositions, however reconcileable they may appear with some parts of the mythology, involve obvious inconsistencies with others. Nor does it seem at all probable, that in those early times, when navigation was so little practised, the advantages of beacon-lights were so generally known and acknowledged, as to render them the objects of mythological allegory.

Colossus of Rhodes.

About three hundred years before the Christian era, Chares, the disciple of Lysippus, constructed the celebrated brazen statue, called the Colossus of Rhodes, which was of such dimensions as to allow vessels to sail into the harbour between its legs, which spanned the entrance. There is considerable probability in the idea, that this figure served the purposes of a lighthouse; but we do not remember any passage in ancient writers, where this use of the Colossus is expressly mentioned There is much inconsistency in the account of this fabric by early writers, who, in describing the distant objects which could be seen from it, appear to have forgotten the height which they assign to the figure. It was partly demolished by an earthquake, about eighty years after its completion; and so late as the year 672 of our era, the brass of which it was composed, was sold by the Saracens to a Jewish merchant of Edessa, for a sum, it is said, equal to L.36,000.

Pharos of Alexandria.

Little is known with certainty regarding the Pharos of Alexandria, which was regarded by the ancients as one of the seven wonders of the world. It was built by Ptolemy Philadelphus, about 300 years before Christ; and it is recorded by Strabo, that the architect Sostratus, the son of Dexiphanes, having first secretly cut his own name on the solid walls of the building, covered the words with plaster, and, in obedience to Ptolemy's command, made the following inscription on the plaster: "King Ptolemy to the gods, the saviours, for the benefit of sailors." What truth there may be in this account of the fraud of Sostratus, there is now no means of determining; and the story is only now interesting, in so far as it shows the object of the royal founder and the use of the tower. The accounts which have reached us of the dimensions of this remarkable edifice, are exceedingly various; and many of the statements regarding the distance at which it could be seen, are clearly fabulous. Josephus approaches nearest to probability, and informs us, that the fire which was kept constantly burning in the top, was visible by seamen at a distance equal to about forty miles. If the reports of some writers are to be believed, this tower must have far exceeded in size the great pyramid itself; but the fact that a building of comparatively so late a date, should have so completely disappeared, whilst the pyramid remains almost unchanged, is a sufficient reason for rejecting, as erroneous, the dimensions which have been assigned by most writers to the Pharos of Alexandria. Some have pretended that large mirrors were employed to direct the rays of the beacon-light on its top, in the most advantageous direction; but there is nothing like respectable evidence in favour of this supposition. Others, with greater probability, have imagined that this celebrated beacon was known to mariners, simply by the uncertain and rude light afforded by a common fire. In speaking of the Pharos,[1] the poet Lucan, on most occasions sufficiently fond of the marvellous, takes no notice of the gigantic mirrors which it is said to have contained. It is true that, by using the word "*lampada*," which can only with propriety be applied to a more perfect mode of illumination than an open fire, he appears to indicate that the "*flammis*" of which he speaks, were not so produced. The word *lampada* may, however, be used metaphorically; and *flammis* would, in this case, not improperly describe the irregular appearance of a common fire. Those who are desirous of knowing all that occurs in ancient authors, on the subject of the Pharos of Alexandria, may consult Pliny, l. xxxvi. c. 12.; l. v. c. 13., and l. xiii c. 11. Strabo, l. xvii. p. 791, et seq. Cæsar, *Comment. de Bell. Civil,* l. iii. Pompon. Mela. l. ii. c. 7. Ammian. Marcellin. l. xxii. c. 16. Joseph. *de Bell. Judaic.* l. vi. Nicolas Lloyd's *Lexicon Geographicum*, and the *Notitia Orbis Antiqui* of Celarius, l. iv. c. 1, p. 13.

Coruna Tower.

Mr. Moore, in his *History of Ireland,* (vol. i. p. 16.) speaks of the Tower of Coruña, which he says is mentioned in the traditionary history of that country, as a lighthouse erected for the use of the Irish in their frequent early intercourse with Spain. In confirmation of this opinion, he cites a somewhat obscure passage from Æthius, the cosmographer. This in all probability is the tower which Humboldt mentions in his Narrative under the name of the *Iron*

---

[1] Septima nox, Zephyro nunquam laxante rudentes,
Ostendit Phariis Ægyptia littora *flammis.*
Sed prius orta dies nocturnam *lampada* texit,
Quam tutas intraret aquas.

Pharsal. ix. 1004.

Tower, which was built as a lighthouse by Caius Saevius Lupus, an architect of the city of Aqua Flavia, the modern Chaves.

Modern history.

Such seems to be the sum of our knowledge of the ancient history of lighthouses, which, it must be admitted, is neither accurate nor extensive. Our information regarding modern lighthouses, is of course more minute in its details, and more worthy of credit, as the greater part of it is drawn from authentic sources, or is the result of the actual observation of the writer of this article, who has visited the most important lighthouses of Europe. It seems sufficient here to notice briefly the most remarkable establishments of the kind now in existence; reserving for the latter part of the article, the more appropriate and important topics of the methods of illumination, and the systems of management.

Tour de Corduan.

The first lighthouse of modern days which merits attention, is the Tour de Corduan, which, in point of architectural grandeur, is unquestionably the noblest edifice of the kind in the world. It is situated on an extensive reef at the mouth of the River Garonne, and serves as a guide to the shipping of Bordeaux and the Languedoc Canal, and indeed of all that part of the Bay of Biscay. It was founded in the year 1584, and was not completed till 1610, under Henri IV. It is minutely described in Belidor's *Architecture Hydraulique*. The building is 197 feet in height, and consists of a pile of masonry, forming successive galleries, enriched with pillasters and friezes, and rising above each other with gradually diminished diameters. These galleries are surmounted by a conical tower, which terminates in the lantern. Round the base is a wall of circumvallation, 134 feet in diameter, in which the light-keepers' apartments are formed, somewhat in the style of casemates. This wall is an outwork of defence, and receives the chief shock of the waves. The tower itself contains a chapel, and various apartments; and the ascent is by a spacious staircase. The first light exhibited in the Tour de Corduan, was obtained by burning billets of oak-wood, in a choffer at the top of the tower; and the use of coal instead of wood, was the first improvement which the light received. A rude reflector, in the form of an inverted cone, was afterwards added, to prevent the loss of light which escaped upwards. About the year 1780, M. Lenoir was employed to substitute reflectors and lamps; and in 1822, the light received its last improvement, by the introduction of the dioptric instruments of M. Fresnel.

Plate I. fig. 7, shews the form of this celebrated lighthouse, and is made from drawings in the possession of the writer of this article, who, in 1834, spent several days there.

Eddystone.

The history of the celebrated lighthouse on the Eddystone rocks is well known to the general reader, from the narrative of Mr. Smeaton the Engineer. These rocks are 9½ miles from the Ram-Head, on the coast of Cornwall; and from the small extent of the surface of the chief rock, and its exposed situation, the construction of the lighthouse was a work of very great difficulty. The first erection was of timber, designed by Mr. Winstanley, and was commenced in 1696. The light was exhibited in November 1698. It was soon found, however, that the sea rose upon this tower to a much greater height than had been anticipated, so much so, it is said, as to "*bury under the water*" the lantern, which was sixty feet above the rock; and Mr. Winstanley was therefore afterwards under the necessity of enlarging the tower, and carrying it to the height of 120 feet. In November 1703, some considerable repairs were required, and Mr. Winstanley, accompanied by his workmen, went to the lighthouse to attend to their execution; but the storm of the 26th of that month, carried away the whole erection, when the engineer and all his assistants unhappily perished.

The want of a light on the Eddystone, soon led to a fatal accident; for not long after the destruction of Mr. Winstanley's lighthouse, the Winchilsea man-of-war was wrecked on the Eddystone rocks, and most of her crew were lost. Three years, however, elapsed, after this melancholy proof of the necessity of a light before the Trinity House of London could obtain a new act to extend their powers; and it was not till the month of July 1706, that the construction of a new lighthouse was begun under the direction of Mr. John Rudyerd of London. On the 28th of July 1708, the new light was first shewn, and continued to be regularly exhibited till the year 1755, when the whole fabric was destroyed by accidental fire, after standing forty-seven years. But for this circumstance, it is impossible to tell how long the lighthouse might, with occasional repair, have lasted, as Mr. Rudyerd seems to have executed his task with much judgment, carefully rejecting all architectural decoration, as unsuitable for such a situation, and directing his attention to the formation of a tower which should offer the least resistance to the waves. The height of the tower, which was of a circular form, and constructed of timber, was, including the lantern, 92 feet, and the diameter at the base, which was a little above the level of high water, was 23.

The advantages of a light on the Eddystone having been so long known and acknowledged by seamen, no time was permitted to elapse before active measures were taken for its restoration; and Mr. Smeaton, to whom application was made for advice on the subject, recommended the exclusive use of stone as the material, which, both from its weight and other qualities, he considered most suitable for the situation. On the 5th of April 1756, Mr. Smeaton first landed on the rock, and made arrangements for erecting a lighthouse of stone, and preparing the foundations, by cutting the surface of the rock into regular horizontal benches, into which the stones were carefully dovetailed or notched. The first stone was laid on 12th June 1757, and the last on the 24th of August 1759. The tower measures 68 feet in height, and 26 feet in diameter at the level of the first entire course, and the diameter under the cornice is 15 feet. The first twelve feet of the tower form a solid mass of masonry, and the stones are united by means of stone joggles, dovetailed joints, and oak treenails. It is remarkable, that Mr. Smeaton should have adopted an arched form for the floors of his building, instead of employing these floors as tie-walls formed of dovetailed stones. To counteract the injurious tendency of the outward thrust of these arched floors, Mr. Smeaton had recourse to the ingenious expedient of laying, in circular trenches or beds in the stones which form the outside casing, sets of chains, which were heated by means of an application of hot lead, and became tight in cooling. The light was exhibited on the 16th October 1759; but such was the state of the lightroom apparatus in Britain at this period, that a feeble light from tallow candles was all that decorated this noble structure. In 1807, when the property of this lighthouse again came into the hands of the Trinity House, on the expiry of a long lease, Argand burners, and parabolic reflectors of silvered copper, were substituted for the chandelier of candles. Plate I. fig. 3, shews a section of the Eddystone lighthouse, as executed according to Mr. Smeaton's design.

Bell-Rock.

The dangerous reef called the Inch Cape, or Bell Rock, so long a terror to mariners, was well known to the earliest navigators of Scotland. Its dangers were so generally acknowledged, that the Abbots of Aberbrothick, from which the rock is distant about twelve miles, caused a float to be fixed upon the rock with a bell attached to it, which being swung by the motion of the waves, served by its tolling to warn the mariner of his approach to the reef. Amongst the many losses which occurred on the Bell-Rock in modern times, one of the most remarkable is that of the York, seventy-four, with all her crew, part of the wreck having been afterwards found on the rock, and part having come ashore on the neighbouring coast. During the survey of the rock also, many instances were discovered of the extent of loss which this reef had occasioned, and many articles of ships' furnishings were picked up on it, as well as various coins, a bayonet, a silver shoe-buckle, and many other small objects. Impressed with the great importance of some guide for the Bell-Rock, Captain Brodie, R.N., set a small subscription on foot, and erected a beacon of spars on the rock, which, however, was soon destroyed by the sea. He afterwards constructed a second beacon, which soon shared the same fate. It was not, however, until 1802, when the Commissioners of Northern Lights brought a bill into Parliament for power to erect a lighthouse on it, that any efficient measures were contemplated for the protection of seamen from this rock, which, being covered at every spring tide to the depth of twelve feet, and lying right in the fareway to the Firths of Forth and Tay, had been the occasion of much loss both of property and life. In 1806, the bill passed into a law, and various ingenious plans were suggested for overcoming the difficulties which were apprehended, in erecting a lighthouse on a rock twelve miles from land, and covered to the depth of twelve feet by the tide. But the suggestion of Mr. Robert Stevenson, the engineer to the Lighthouse Board, after being submitted to the late Mr. Rennie, was at length adopted; and it was determined to construct a tower of masonry, on the principle of the Eddystone. On the 17th of August 1807, Mr. Stevenson accordingly landed with his workmen, and commenced the work by preparing the rock to receive the supports of a temporary wooden pyramid, on which a barrack-house, for the reception of the workmen, was to be placed; and during this operation, much hazard was often incurred in transporting the men from the rock, which was only dry for a few hours at spring tides, to the vessel which lay moored off it. The lowest floor of this temporary erection, in which the mortar for the building was prepared, was often broken up and removed by the force of the sea. The foundation having been excavated, the first stone was laid on the 10th July 1808, at the depth of sixteen feet below the high-water of spring-tides, and at the end of the second season, the building was five feet six inches above the lowest part of the foundation. The third season's operations terminated by finishing the solid part of the structure, which is thirty feet in height; and the whole of the masonry was completed in October 1810. The light was first exhibited to the public on the night of the 1st of February 1811. The difficulties and hazards of this work, were chiefly caused by the short time during which the rock was accessible between the ebbing and flowing tides; and amongst the many eventful incidents which render the history of this work interesting, was the narrow escape which the engineer and thirty-one persons made from being drowned, by the rising of the tide upon the rock, before a boat came to their assistance, the attending vessel having broken adrift. This circumstance occurred before the barrack-house was erected, and is narrated by Mr. Stevenson in his account of the work, published at the expense of the Lighthouse Board in 1824, to which we may refer for more minute information on the subject of this work, and the other lights of the coast of Scotland.

The Bell-Rock Tower is 100 feet in height, 42 feet in diameter at the base, and 15 at the top. The door is 30 feet from the base, and the ascent is by a massive copper ladder. The apartments, including the lightroom, are six in number. The light is a revolving red and white light, and is produced by the revolution of a frame containing twenty Argand lamps, placed in the foci of parabolic mirrors, arranged on a quadrangular frame, whose alternate faces have shades of red glass placed before the reflectors, so that a red and white light is shewn successively. The machinery, which causes the revolution of the frame containing the lamps, is also applied to tolling two large bells, to give warning to the mariner of his approach to the rock in foggy weather. Plate I. fig. 6, shews a section of the Bell-Rock Lighthouse, and an elevation of the temporary barrack-house, which was removed on the completion of the work.

Carlingford

The most remarkable lighthouse on the coast of Ireland is that of Carlingford, near Cranfield Point, at the entrance of Carlingford Lough. It was built according to the design of Mr. George Halpin, the Inspector of the Irish Lights; and was a work of an arduous nature, being founded twelve feet below the level of high-water on the Hawlbowling Rock, which lies about two miles off Cranfield Point. The figure is that of a frustum of a cone, 111 feet in height, and 48 feet in diameter at the base. The light, which is fixed, is from oil burned in Argand lamps placed in the foci of parabolic mirrors. It was first exhibited on the night of the 20th December 1830.

Skerryvore

The Commissioners of the Northern Lighthouses have lately taken measures for erecting a lighthouse on the rock of Skerryvore, which lies in the channel between the Western Isles of Scotland and the north of Ireland. The solid rock is only about 40 yards square, and is about 13 miles from the nearest point of the Island of Tyree. It is exposed to the unbroken fury of the Atlantic, there being no land between it and the coast of America. The works were commenced last season on the rock, by the erection of part of a wooden barrack for the reception of the workmen, during the building of the tower of masonry. This barrack, which resembled that of the Bell-Rock, shewn in Plate I. fig. 6, disappeared on the night of the 3d November 1838; and when the writer of this article visited the rock, on the 16th of the same month, only a single beam remained. Several spars of a large vessel, and some of the beams of the barrack, afterwards came ashore on the Islands of Tyree and Coll; a circumstance which has led to the belief, that the fabric had sustained some injury by the collision of some heavy body in motion. From the tremendous height to which the sea was observed to rise on the rock, there is, on the other hand, some reason to suspect that the fury of the waves alone may have demolished the unfinished structure of the barrack. The works were resumed in the spring of 1839.

There are various other lighthouses which, in themselves, are sufficiently deserving of a separate notice, were it not that they have, more or less, something in common with those already described, which are unquestionably the most remarkable edifices of the kind. We shall, therefore, now proceed to consider the methods of illumination, which have been adopted in lighthouses; a subject to which much attention has of late years been directed, and which is the most important consideration connected with those establishments, whose utility depends solely upon the distance at which the light can be seen, and the facility with which the mariner can recognise their individual appearance as indicative of a particular part of the coast.

Coal lights

There can be little doubt, that down to a very late period, the only mode of illumination adopted in the lighthouses, even of the most civilized nations of Europe, was the combustion of wood or coal in a chauffer on the top of a high tower. It is needless to enlarge upon the evils of such a method; they need only be named to be understood; for it is difficult to conceive how an efficient system of lighting a coast could be managed under such disadvantages. The uncertainty caused by the effects of wind and rain, and the impossibility of rendering one light distinguishable from another, must have, at all times, rendered the early lighthouses, in a great measure, useless to the mariner.

Catoptric[1] system.

M. Teulère, a member of the Royal Corps of Engineers of Bridges and Roads in France, is, by some, considered the first who hinted at the advantages of parabolic reflectors; and he is said, in a memoir dated the 26th June 1783, to have proposed their combination with Argand lamps, ranged on a revolving frame, for the Corduan lighthouse. Whatever foundation there may be for the claim of M. Teulère, certain it is, that this plan was actually carried into effect at Corduan under the directions of the Chevalier Borda, and to him is generally awarded the merit of having conceived the idea of applying parabolic mirrors to lighthouses. These were prodigious steps in the improvement of lighthouses, as not only the power of the lights was thus greatly increased, but the introduction of a revolving frame proved a valuable source of distinction amongst lights, and has since been the means of greatly extending their utility. The exact date of the change on the light of the Corduan is not known; but as it was made by Lenoir, the same young artist to whom Borda about the year 1780, intrusted the construction of his reflecting circle, it has been conjectured by some, that the improvement was made about the same time. If this conjecture be correct, the claim of M. Teulère must of course fall to the ground. The reflectors were formed of sheet-copper, plated with silver, and had a double ordinate of 31 French inches. It was not long before these improvements were adopted in England, by the Trinity House of London, who sent a deputation to France to inquire into their nature. In Scotland, one of the first acts of the Northern Lights Board in 1786, was to substitute reflectors in the room of coal-lights, then in use at the Isle of May in the Firth of Forth, and the Cumbrae Isle in the Firth of Clyde, which had, till that period, been the only beacons on the Scotch coast. The reflectors employed were formed of facets of mirror glass, placed in hollow parabolical moulds of plaster, according to the designs of the late Mr. Thomas Smith, the engineer of the board, who, as appears from the article *Reflector* in the Supplement to the third edition of the Encyclopædia Britannica, was not aware of what had been done in France, and had, himself, conceived the idea of this combination. The system of Borda was also adopted in Ireland, and in time, variously modified, it became general wherever lighthouses were known.

---

[1] From the Greek *κατοπτρον, a mirror,* a compound of *κατα, opposite to,* and *ὄπτομαι, I see.*

Paraboloidal mirrors.

The property of the parabola, by which all lines incident on its surface from the focus make with normals to the curve at the points of incidence, angles equal to the inclination of these same normals respectively to lines drawn parallel to the axis of the curve, is that which fits it for the purposes of a lighthouse. A hollow mirror, formed by the revolution of a portion of a parabola about its axis, has, in consequence of this property, the power of projecting the repeated images of a luminous point placed in its focus, in directions parallel to the axis of the generating curve, so that when the mirror is placed with its axis parallel to the horizon, a cylindric beam of light is thereby sent forward in a horizontal direction. When such mirrors are placed side by side, with their axes parallel on the faces of a quadrangular frame which revolves about a vertical axis, a distant observer receives the successive impressions which result from the passage of each face of the frame, over a line drawn between the observer's eye and the centre of the revolving frame. This arrangement constitutes what is called a revolving light. A fixed light is produced by placing side by side, round a fixed circular frame, a number of reflectors, with their axes inclined to each other, so as to be radii containing equal arcs of the frame on which they are placed. It is obvious that a perfect parabolic figure, and a luminous *point* mathematically true, would render the illumination of the whole horizon by means of a fixed light *impossible;* and it is only from the aberration caused by the size of the flame which is substituted for the point, that we are enabled to render even revolving lights practically useful. But for this aberration, even the slowest revolution in a revolving light, which would be consistent with a continued observable series, such as the practical seamen could follow, would render the flashes of a revolving light greatly too transient for any useful purpose; whilst fixed lights being visible in the azimuths only in which the mirrors are placed, would, over the greater part of the distant horizon, be altogether invisible. The size of the flame, therefore, which is placed in the focus of a parabolic mirror, when taken in connexion with the form of the mirror itself, leads to those important modifications in the paths of the rays, and the form of the resultant beam of light, which have rendered the catoptric system of lights so great a benefit to the benighted seaman.

It is obvious, from a consideration of the nature of the action which takes place in this combination of the paraboloidal mirrors with Argand lamps, that the revolving light is not only more perfect in its nature than the fixed light, but that it possesses the advantage of being susceptible of an increase of its power, by increasing the number of reflectors, which have their axes parallel to each other, so as to concentrate the effect of several mirrors in one direction. The perfect parallelism of the axes of separate mirrors, it is true, is unattainable, but approaches may be made sufficiently near for practical results; and in order to prolong the duration of the flash, the reflectors are sometimes placed on a frame, having each of its sides slightly convex, by which arrangement, the outer reflectors of each face of the frame have their axes less inclined inwards from the radii of the revolving frame which pass through their foci.

Proportions and divergence of paraboloidal mirrors.

The best proportions for the paraboloidal mirrors, depend upon the object to which they are to be applied; as mirrors which are intended to produce great divergence in the form of the resultant beam should have one form; whilst those which are designed to cause a near approach to parallelism of the rays, will have another form. These objects may also be attained by variations of the size of the flame applied in the same mirror, but it is much more advantageous to produce the effect, by a change in the form of the mirror, as any increase of the flame beyond the size which is found to be most advantageous in other respects, cannot be regarded otherwise than as a wasteful expenditure of light. The details into which a full investigation of this matter would lead us, are quite beyond the scope of this article, and it therefore seems sufficient to give the formulæ which express the relations which exist between the size of the flame, the reflecting surface, and the corresponding divergence of the reflected ray. If Δ represent the inclination of any reflected ray to the axis of a paraboloidal mirror, e the distance of the focus from the point of reflection, and d the distance from the edge of the flame to the focus in the plane of reflection, we shall have $\sin \Delta = \frac{d}{e}$, and when the flame in the given plane of reflection is circular, or has its opposite sides equi-distant from the focus of the mirror, we shall, by putting Δ' for the effective divergence of the mirror in the given plane, have $\Delta' = 2\,\Delta$. When, therefore, great divergence, as in the case of the fixed lights, is required, the prolate form of the curve is to be preferred; and the oblate is conversely more suited to revolving lights.

Power of paraboloidal mirrors.

The power of the reflectors ordinarily employed in lighthouses, is generally equal to about 360 times the effect of the unassisted flame which is placed in the focus. This value, however, is strictly applicable only at the distances at which the observations have been made, as the proportional value of the reflected beam must necessarily vary with the distance of the observer, agreeably to some law dependent upon the unequal distribution of the light in the luminous cone which proceeds from it. The ordinary burners used in lighthouses are one inch in diameter, and the focal distance generally adopted is four inches, so that the effective divergence of the mirror in the horizontal plane may be estimated at about 14° 22′. In arranging reflectors on the frame of a fixed light, however, it would be advisable to calculate upon less effective divergence, for beyond 11° the light is feeble; but the difficulty of placing many mirrors on one frame, and the great expense of oil required for so many lamps, have generally led to the adoption of the first valuation of the divergence.

Manufacture and testing of reflectors.

The reflectors used in the best lighthouses, are made of sheet copper plated in the proportion of 6 oz. of silver to 16 oz. of copper. They are moulded to the paraboloidal form, by a delicate and laborious process of beating with mallets and hammers of various forms and materials, and are frequently tested during the operation by the application of a carefully-formed mould. After being brought to the curve, they are stiffened by means of a strong bizzle, and a strap of brass which is attached to it for the purpose of preventing any accidental alteration of its figure. Polishing powders are then applied, and the instrument receives its last finish.

Two guages of brass are applied to test the form of the reflector. One is for the back, and is used by the workmen during the process of hammering, and the other is applied to the concave face as a test, while the mirror is receiving its final polish. It is then tested, by trying a burner in the focus, and measuring the intensity of the light at various points of the reflected conical beam. Another test may also be applied successively to various points in the surface, by masking the rest of the mirror. Having placed a screen in the line of the axis of the mirror at some given distance from it, it is easy to find whether the image of a very small object placed in the conjugate focus, which is due to the distance of the screen, be reflected at any distance from that point on the centre of the screen through which the prolongation of the axis of the mirror would pass, and thus to obtain a measure of the error of the instrument. For this purpose, it is necessary to find the position of the conjugate focus, which corresponds to the distance of the screen. If b be the distance which the object should be removed outwards from the principal focus of the mirror, d the distance from the focus to the screen, and r the distance from the focus to the point of the mirror which is to be tested, we shall have $b=\frac{r^2}{d}$ as the distance which the object must be removed outwards from the true focus on the line of the axis.

Argand lamps used in reflectors.

The flame generally used in reflectors, is from an Argand fountain-lamp, whose wick is an inch in diameter. Much care is bestowed upon the manufacture of these lamps for the Northern Lighthouses, which have their burners tipped with silver, to prevent wasting by the great heat which is evolved. These burners are also fitted with a slide apparatus, accurately formed, by which the burner may be removed from the interior of the mirror at the time of cleaning it, and returned exactly to the same place, and locked by means of a key. This arrangement, which is shewn in Plate II. figs. 7, 8, and 9, is very important, as it insures the burner always being in the focus, and does not require that the reflector be lifted out of its place every time it is cleaned; so that, when once carefully set and screwed down to the frame, it is never altered. In these figs. *a a a* represents one of the reflectors, *b* is the lamp, *c* is a cylindric fountain, which contains 24 oz. of oil. The oil-pipe, and fountain of the former, is connected with the rectangular frame *d*, and is moveable in a vertical direction upon the guide rods *e* and *f*, by which it can be let down and taken out of the reflector, by simply turning the handle *g*, as will be more fully understood by examining fig. 8. An aperture of an elliptical form, measuring about two inches by three, is cut in the upper and lower part of the reflector, the lower serving for the free egress and ingress of the lamp, and the upper, to which the copper tube *h* is attached, serving for ventilation; *i* shews a cross section of the main bar of the chandelier or frame, on which the reflectors are ranged, each being made to rest on knobs of brass, one of which, as seen at *k k*, is soldered on the brass band *l*, that clasps the exterior of the reflector.

Plate II. fig. 8, is a section of the reflector *a a*, shewing the position of the burner *b*, with the glass chimney *b′*, and oil-cup *l*, which receives any oil that may drop from the lamp.

Plate II. fig. 7, shews the apparatus for moving the lamp up and down, so as to remove it from the reflector at the time of cleaning it. In the diagram, *c*, the fountain, is moved partly down; *d*, *d* shews the rectangular frame on which the burner is mounted, *e e* the elongated socket-guides, *f* the rectangular guide-rod, connected with the perforated sockets on which the *checking-handle g* slides.

Arrangement of reflectors on the frame.

The modes of arranging the reflectors in the frames, are shewn in Plate I. figs. 2, 4, and 5. It seems quite unnecessary, after what is said on the subject of divergence, to do more than remark, that in revolving lights the reflectors are placed with their axes parallel to each other, so as to concentrate their power in one direction; whilst in fixed lights, it is necessary, in order to effect as equal a distribution of the light over the horizon as possible, to place the reflectors, with their axes inclined to each other, at an angle somewhat less than that of the divergence of the reflected cone. For this purpose, a brass guage, composed of two long arms, somewhat in the form of a pair of common dividers, connected by means of a graduated limb, is employed. The arms having been first placed at the angle, which is supplemental to that of the inclination of the axes of the two adjacent mirrors, are made to span the faces of the reflectors, one of which is moved about till its edges are in close contact with the flat surface of one of the arms of the guage. The different arrangements of the reflectors will be more fully understood by referring to the Plates.

Plate I. figs. 2 and 5, shew an elevation and plan of a revolving apparatus on the catoptric principle. In these figures, *n n* shews the reflector frame or chandelier; *o o*, the reflectors with their oil-fountains *p p*. The whole is attached to the revolving axis or shaft *q*. The copper tubes *r r* convey the smoke from the lamps; *s s* are cross bars which support the shaft at *t t*; *u u* is a copper pan for receiving any moisture which may accidentally enter at the central ventilator in the roof of the light-room; *l* is a cast-iron bracket, which supports the pivot on the shaft; *m m* are bevelled wheels, which convey motion from the machine to the shaft.

Plate I. fig. 4, shews a plan of one tier of reflectors arranged in the manner employed in a fixed catoptric light; *n n* shews the chandelier, *q* the fixed shaft in the centre, which supports the whole, *o o* the reflectors, and *p p* the fountains of their lamps.

Bordier Marcet's reflectors.

A variety of the parabolic reflectors has been invented by M. Bordier Marcet, the pupil and successor of Argand, who has laboured with much enthusiasm in perfecting catoptric instruments, more especially with a view to their application in the illumination of lighthouses and the streets of towns. Amongst many other ingenious combinations of parabolic mirrors, he has invented and constructed an apparatus, which is much used in harbour-lights on the French coast. The object of this apparatus is to fulfil, as economically as possible, the conditions required in a fixed light, by illuminating, with perfect equality, every part of the horizon, by means of a single burner; and M. Bordier Marcet has in his work-shop an instrument of this kind, eight feet in diameter, which he constructed on speculation. The apparatus used in harbour-lights, on the French coast, is of much smaller dimensions, and does not exceed fifteen inches in diameter. A perfect idea of the construction and effect of this apparatus, may be formed, by conceiving a parabola to revolve about its parameter as an axis, so that its upper and lower limbs would become the generating lines of two surfaces possessing the property of reflecting, in lines parallel to the axis of the parabola, all the rays incident upon them, from a light placed in the point where the parameter and axis of the generating parabola intersect each other. This point being the focus of each parabolic section of this apparatus, the light is equally dispersed in every point of the horizon, when the axes of the parabolic sections are in a plane perpendicular to a vertical line. But however perfectly this apparatus may attain this important object, it does so at the sacrifice of the most efficient part of the parabolic surface, which lies between the vertex and the parameter; and, therefore, produces a proportionally feeble effect. This beautiful little instrument is shewn in Plate II, fig. 5; in which b shews the burner p, p the upper reflecting surface, and p' p' the lower reflecting surface, both generated in the manner above described by the revolution of a parabola about its parameter x b; F is the focus of the generating parabola; and l l are small pillars, which connect the two reflecting plates, and give strength to the apparatus.

M. Bordier Marcet has also prepared a very ingenious modification of the paraboloidal mirror, which he has described under the name of *fanal à double aspect;* and the object of which is, to obtain a convenient degree of divergence from parabolic mirrors, by the use of two flames and two reflecting surfaces, each of which is acted upon by its own flame, and also by that of the other. This modification consists in the union of two portions of hollow paraboloidal mirrors, generated by the revolution of two parabolas about a common horizontal axis, and illuminated by two lamps placed in the focus of each. The first surface is generated by the revolution on its axis of a segment of a paraboloid intercepted between the parameter and some double ordinate greater than it, and may, from its form, be called the ribbon-shaped mirror. The second surface is that of a parabolic conoid, which is cut off by a vertical plane passing through a double ordinate, which is equal to the parameter of the parabolic ribbon, which is placed in front of it. The elements of the curve which forms the conoidal mirror, must be so chosen as to have its focus at a convenient distance in front of that of the ribbon-shaped mirror, so as to admit of placing the two lamps separate from each other, as well as to produce the necessary degree of divergence, which is to be obtained by the action of these mirrors respectively on the flame placed in the focus of the other. These two mirrors are thus joined together. Each mirror produces, by means of the lamp placed in its focus, an approach to parallelism of the reflected rays, which M. Bordier Marcet has not inaptly termed the *principal effect;* whilst the action of each surface on the lamp which is placed in the focus of the other, causes what the inventor calls the *secondary* or *lateral effect.* Their secondary action may be described thus: The lamp, which is in the focus of the ribbon, is much nearer the vertex of the conoid than its own focus; so that its rays making, with normals to the surface of the conoid, angles greater than those which are formed by the rays proceeding from its focus, are of necessity reflected in lines diverging from the axis of the mirror. Those, on the contrary, which proceed from the focus of the conoid, meet the ribbon-shaped surface, so as to make angles with its normals more acute than those which the rays from its own focus could do, and which are, therefore, reflected in lines converging to the axis of the mirror. These reflected rays must therefore cut the axis, and diverge from it on the other side. This apparatus has been tried with success at La Hève and some other lights on the French coast. But it is impossible not to perceive the great loss of light which results from the use of two flames in one mirror; and it must not be forgotten, that the divergence which is obtained is not confined to the horizontal direction in which only it is wanted; but the light is scattered in every direction round the edge of the mirror.

Spherical mirrors.

Spherical mirrors have been employed in lighthouses only when they can be introduced as subsidiary parts in dioptric apparatus; and any observations regarding them will, therefore, be made in treating of the dioptric lights of Fresnel.

Floating lights.

Floating lights are only resorted to in cases of absolute necessity, as their maintenance is extremely expensive, whilst they are less to be relied on, and, in all respects, less efficient than land lights. They are large vessels, built with great breadth of beam, and are generally moored off shoals, or serve as guides for taking channels. The lights are from lamps placed in front of small reflectors, ranged in lanterns, which are hoisted on the masts of the vessel. The number of lights varies from one to three as the only means of distinction, the feebleness of the light generally rendering it inexpedient to adopt the distinctions derived from the use of coloured media.

Distinctions of catoptric lights.

Catoptric lights are susceptible of nine separate distinctions, which are called *fixed, revolving white, revolving red and white, revolving red with two whites, revolving white with two reds, flashing, intermittent, double fixed lights, and double revolving white lights.* The first exhibits a steady and uniform appearance, which is not subject to any change; and the reflectors used for it, (as already noticed), are of smaller dimensions than those employed in revolving lights. This is necessary in order to permit them to be ranged round the circular frame, with their axes inclined at such an angle, as shall enable them to illuminate every point of the horizon. The revolving light is produced by the revolution of a frame with three or four sides, having reflectors of a large size grouped on each side, with their axes parallel; and as the revolution exhibits a light gradually increasing to *full strength,* and in the same gradual manner decreasing to total darkness, its appearance is extremely well marked. The succession of *red* and *white* lights is caused by the revolution of a frame whose different sides present red and white lights; and these, as already mentioned, afford three separate distinctions, namely, alternate, red, and white; the succession of two white lights after one red, and the succession of two red lights after one white light. The *flashing* light is produced in the same manner as the *revolving* light; but owing to a different construction of the frame, and the greater quickness of the revolution, a totally different and very striking effect is produced. The brightest and darkest periods being but momentary, this light is characterised by a rapid succession of bright flashes, from which it gets its name. The *intermittent* light is distinguished by bursting suddenly into view and continuing steady for a short time, after which it is suddenly eclipsed for half a minute. This striking appearance is produced by the perpendicular motion of circular shades in front of the reflectors, by which the light is alternately hid and displayed. This distinction, as well as that called the *flashing light,* are peculiar to the Scotch coast, having been first introduced by the present Engineer of the Northern Lights Board. The double lights, which are generally used only where there is a necessity for a *leading* line, as a guide for taking some channel or avoiding some danger, are exhibited from two towers, one of which is higher than the other; and when seen in one line, form a direction for the course of shipping. At the Calf of Man, a striking variety has been introduced into the character of leading lights, by substituting, for two *fixed* lights, two lights which revolve in the same periods, and exhibit their flashes at the same instant; and these lights are, of course, susceptible of the other variety enumerated above, that of two revolving red and white lights revolving in equal periods. The utility of all these distinctions is chiefly to be imputed to their at once striking the eye of an observer and being instantaneously obvious to strangers.

[1]Dioptric system of Fresnel.

Before entering upon the subject of the dioptric lights, the writer of this article embraces with pleasure the opportunity afforded to him, of acknowledging the liberality of M. Léonor Fresnel, the present Secretary of the Lighthouse Commission of France. It was entirely owing to the readiness with which M. Fresnel afforded him access to every avenue of information on the subject of lighthouses, that he was enabled to effect the object of a mission to France, on which he was sent in the year 1834, by the Commissioners of Northern Lights.

The first proposal of applying lenses to lighthouses, is recorded by Smeaton in his account of the Eddystone Lighthouse, where he mentions that, in 1759, an optician in London proposed grinding the glass of the lantern to a radius of seven feet six inches; but the description is too vague to admit of even a conjecture regarding the proposed arrangement of the apparatus. Above forty years ago, however, lenses were actually tried in several lighthouses in the south of England; but their imperfect figure, and the quantity of light absorbed by the glass, which was of inferior quality and of considerable thickness, rendered their effect so much inferior to that of the parabolic reflectors then in use, that, after trying some strange combinations of lenses and reflectors, the former were finally abandoned.

The object to be attained by the use of lenses in a lighthouse, is, of course, identical with that which is answered by employing reflectors; and both instruments effect the same end by different means, collecting the rays which diverge from a point called the *focus*, and projecting them forward in a beam, whose axis coincides with the produced axis of the instrument. The actions by which these similar results are effected, have been termed *reflection* and *refraction*. In the one case, the light, as has been already said, merely impinges on the reflecting surface, and is thrown back; whilst in the other, the rays pass through the refracting medium, and are bent or refracted from their natural course.

Polyzonal lenses.

The celebrated Buffon, to prevent the great absorption of light by the thickness of the material, which would necessarily result from giving to a lens of great dimensions a figure continuously spherical, proposed to grind out of a solid piece of glass, a lens in steps or concentric zones. This suggestion of Buffon regarding the construction of large burning glasses, was first executed, with tolerable success, about the year 1780, by the Abbé Rochon; but such are the difficulties attending the process of working a solid piece of glass into the necessary form, that it is believed the only other instrument ever constructed in this manner, is that which was made by Messrs. Cookson of Newcastle-upon-Tyne, for the Commissioners of Northern Lighthouses.

The merit of having first suggested the building of these lenses in separate pieces, seems to be due to Condorcet, who in his *Eloge de Buffon*, published so far back as 1773, enumerates the advantages to be derived from this method.[2] Sir David Brewster also described this mode of building lenses in 1811, in the *Edinburgh Encyclopædia;* and in 1822, the late eminent Fresnel, alike unacquainted with the suggestions of Condorcet, or the description by Sir David Brewster, explained with many ingenious and interesting details, the same mode of constructing these instruments. To Fresnel belongs the additional merit of having first followed up his invention, by the construction of a lens, and in conjunction with MM. Arago and Mathieu of placing a powerful lamp in its focus, and indeed of finally applying it to the practical purposes of a lighthouse. The fertile genius of the French Academician has produced many ingenious combinations of dioptric instruments for lighthouses, which we shall have occasion to notice in the sequel.

Annular lenses.

The great advantages which attend the mode of construction proposed by Condorcet, are, the ease of execution, by which a more perfect figure may be given to each zone, and spherical aberration almost entirely corrected, and the power of forming a lens of larger dimensions than could easily be made from a solid piece. Both Buffon and Condorcet, however, chiefly speak of reducing the thickness of the material, and do not seem to have thought of determining the radius and centre of the curvature of the generating arcs of each zone, having contented themselves with simply depressing the spherical surface in separate portions. Fresnel, on the other hand, determined these centres, which constantly recede from the axis of the lens in proportion as the zones to which they refer are removed from its centre; and the surfaces of the zones of the annular lens, consequently, are not parts of concentric spheres, as in Buffon's lens. It deserves notice, that the first lenses constructed for Fresnel by M. Soleil had their zones polygonal, so that the surfaces were not annular, a form which Fresnel considered less accommodated to the ordinary resources of the optician. He also, with his habitual penetration, preferred the plano-convex to the double-convex form, as more easily executed. After mature consideration, he finally adopted crown glass, which, notwithstanding its greenish colour, he considered more suitable than flint glass, as being less liable to *striæ*. All his calculations were made in reference to an index of refraction of 1·51, which he had verified by repeated experiments, conducted with that patience and accuracy for which, amidst his higher qualities, he was so remarkably distinguished. These instruments have received the name of *annular* lenses, from the figure of the surface of the zones.

Fig. 6, Plate II, exhibits a plan and section of an annular lens of the largest size, whose focal distance is 92 centimètres, or about 36·22 inches, and which subtends a luminous pyramid of 46° of inclination, having its apex in the flame.

Cylindric refractors

Having once contemplated the possibility of illuminating lighthouses by dioptric means, Fresnel quickly perceived the advantage of employing for fixed lights a lamp placed in the centre of a polygonal hoop, consisting of a series of cylindric refractors, *infinitely small* in their length, and having their axes in planes parallel to the horizon.

Such a continuation of vertical cylindric sections of various curvatures, by refracting the rays proceeding from the focus only in a direction perpendicular to the vertical sections of the cylindric parts, must distribute a zone of light *equally brilliant* in every point of the horizon. This effect will be easily understood, by considering the middle vertical section of one of the great annular lenses or burning glasses, already described, abstractly from its relation to the rest of the instrument. It will readily be perceived that this section possesses the property of simply refracting the rays at right angles to the line of the section, or in a direction parallel to the horizon, and cannot collect the rays from either side of the vertical line; and if this section, by its revolution about a vertical axis, becomes the generating line of the enveloping hoop, above noticed, such a hoop would of course possess the property of refracting an equally diffused zone of light round the horizon. The difficulty, however, of forming this apparatus, appeared so great, that Fresnel determined to substitute for it a vertical polygon, composed of what have been improperly called *cylindric lenses*, but which in reality are mixtilinear and horizontal prisms, distributing the light which they receive from the focus, equally over the horizontal sector which they subtend. This polygon has a sufficient number of sides to enable it to give at the angle formed by the junction of two of them, a light not very much inferior to what is produced by one of the sides; and upper and lower courses of curved mirrors, are so placed as to make up for the deficiency of the light at the angles. The effect sought for in a fixed light is thus obtained in a much more perfect manner, than by any combination of the parabolic mirrors used in the British lighthouses.

---

[1] In all probability directly derived from the Greek *διόπτρα*, an optical instrument with holes for looking through, which is a compound of *διὰ*, *through*, and *ὄπτομαι*, *I see.*

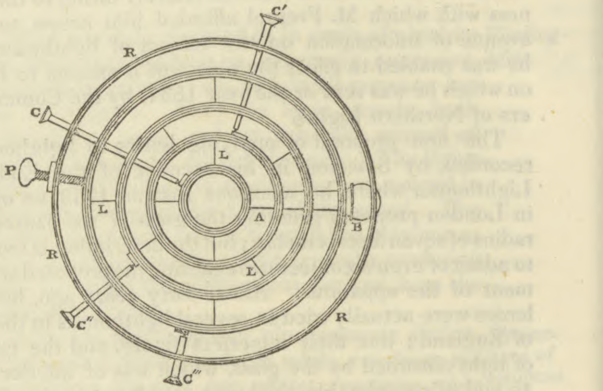
[2] On pourrait même composer de plusieurs pièces ces loups à échelons; on y gagnerait plus de facilité dans la construction, une grande diminution de dépense, l'avantage de pouvoir leur donner plus d'étendue, et celui d'employer suivant le besoin un nombre des cercles plus ou moins grand, et d'obtenir ainsi du même instrument différens dégrès de force. *Eloge de Buffon*, p. 35. *Œuvres de Condorcet*, tom. iv. Paris, 1804.

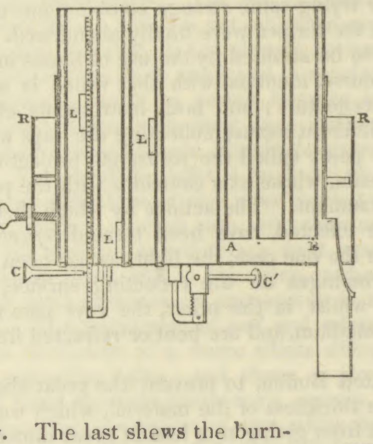
An ingenious modification of the fixed apparatus is due to the inventive mind of Fresnel, who also conceived the happy idea of placing one apparatus of this kind in front of another, with the axes of the cylindric pieces crossing each other at right angles. As these cylindric pieces have the property of refracting all the rays which they receive from the focus, into a direction perpendicular to the mixtilinear section which generates them, it is obvious that if two refracting media of this sort be arranged as proposed by Fresnel, their joint action will unite the rays which come from their common focus into a beam, whose sectional area is equal to the overlapped surface of the two instruments, and thus produce the effect of an annular lens. It was by availing himself of this property of crossed prisms, that Fresnel invented the distinction for lights, which he calls *a fixed light varied by flashes;* in which the flashes are caused by the revolution of cylindric media, with vertical axes round the fixed-light apparatus already described.

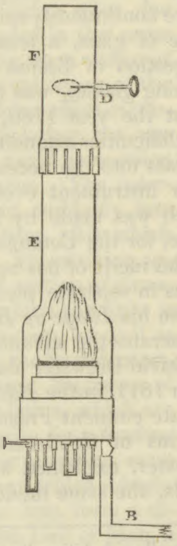
Mechanical lamp.

Fresnel immediately perceived the necessity of combining with the dioptric instruments which he had invented, a burner capable of producing a large volume of flame; and the rapidity with which he matured his notions on this subject, and at once produced an instrument admirably adapted for the end he had in view, affords one of the many proofs of that happy union of practical with theoretical talent, for which he was so distinguished. Fresnel himself has modestly attributed much of the merit of the invention of this lamp to M. Arago; but this gentleman, with great candour, gives the whole credit to his deceased friend, in a notice regarding lighthouses, which appeared in the *Annuaire du Bureau des Longitudes* of 1831. The lamp has four concentric burners, which are defended from the action of the excessive heat, produced by their united flames, by means of a superabundant supply of oil, which is thrown up from the cistern below by a clock-work movement, and constantly overflows the wicks, as in the mechanical lamp of Carcel. A very tall chimney is found to be necessary, in order to supply fresh currents of air to each wick with sufficient rapidity to support the combustion. The carbonisation of the wicks, however, is by no means so rapid as might be expected, and it is even found that after they have suffered a good deal the flame is not sensibly diminished, as the great heat evolved from the mass of flame, promotes the rising of the oil in the cotton. The writer of this article has seen the large lamp at the Tour de Corduan burn for seven hours without being snuffed, or even having the wicks raised.

The annexed diagrams will give a more perfect idea of the nature of the concentric burner than can easily be conveyed by words alone. The first shews a plan of a burner of four concentric wicks. The intervals which separate the wicks from each other and allow the currents of air to pass, diminish in width a little, as they recede from the centre. The next shews a section of this burner. C, C′, C″, C‴ are the rack handles for raising or depressing each wick, AB is the horizontal duct which leads the oil to the four wicks, L, L, L, are small plates of tin by which the burners are soldered to each other, and which are so placed as not to hinder the free passage of the air; P is a clamping screw, which keeps at the proper height the gallery R, R, which carries the chimney. The last shews the burner with its glass chimney and damper. E is the glass chimney, F is a sheet-iron cylinder, which serves to give it a greater length, and has a small damper D, capable of being turned by a handle for regulating the supply of air; and B is the pipe which supplies the oil to the wicks. The great risk in using this lamp arises from the leather valves that force the oil by a clock-work movement, being occasionally liable to derangement; and several of the lights on the French coast, and more especially the Corduan, have been extinguished by the failure of the lamp for a few minutes, an accident which has never, and scarcely can happen with the fountain lamps which illuminate the reflectors. To prevent the occurrence of such accidents, and to render their consequences less serious, various precautions have been resorted to. Amongst others, an alarum is attached to the lamp, consisting of a small cup pierced in the bottom, which receives part of the overflowing oil from the wicks, and is capable, when full, of balancing a weight placed at the opposite end of a lever. The moment the machinery stops, the cup ceases to receive the supply of oil, and the re-







mainder running out at the bottom, the equilibrium of the lever is destroyed, and in falling, it disengages a spring which rings a bell sufficiently loud to waken the keeper should he chance to be asleep. It may justly be questioned whether this alarum would not prove a temptation to the keepers to relax in their watchfulness and fall asleep. There is another precaution of more importance, which consists in having always at hand in the light-room a spare lamp trimmed and adjusted to the height for the focus, which may be substituted for the other in case of accident. It ought to be noticed, however, that it takes about twenty minutes from the time of applying the light to the wicks to bring the flame to its full strength, which, in order to produce its best effect, should stand at the height of nearly four inches ($10^{\text{cm.}}$). The inconveniences attending this lamp have led to several attempts to improve it; and amongst others M. Delaveleye has proposed to substitute a pump having a metallic piston, in place of the leather valves, which require constant care, and must be frequently renewed. A lamp was constructed in this manner by M. Lepaute, and tried at Corduan; but was afterwards discontinued until some further improvements could be made upon it. It has lately been much improved by M. Wagner, an ingenious artist whom M. Fresnel employed to carry some of his improvements into effect. In the dioptric lights on the Scotch coast, a common lamp with a large wick is kept constantly ready for lighting; and in the event of the sudden extinction of the mechanical lamp by the failure of the valves, it is only necessary to unscrew and remove its burner, and put the reserve-lamp in its place. The height of this lamp is so arranged, that its flame is in the focus of the lenses, when the lamp is placed on the ring which supports the burner of the mechanical lamp; and as its flame, though not very brilliant, has a considerable volume, it will answer the purpose of maintaining the light for an hour or two, until the light-keepers have time to repair the valves of the mechanical lamp. No occasion for the use of this reserve-lamp has yet occurred.

Mr. Oldham's lamp.

The lamp invented by Mr. Oldham of Dublin, appears, from the simplicity of its construction, to be very suitable for the purposes of a lighthouse; and the writer of this article is at present engaged in some experiments to ascertain the possibility of applying the pressure used in Mr. Oldham's lamp to produce the same regular supply of oil to the concentric burner, which is at present effected by means of the mechanism of the French lamp.

Divergence of the annular lenses.

The divergence of the annular lens is greatly less than that of the parabolic mirror. It may be estimated in the following manner. Let Δ be the angle of divergence of any ray emerging from the lens, l the distance of the point of incidence from the principal focus of the lens, and r the radius of the flame, and we have $\sin. \Delta = \frac{r}{l}$, and when Δ' is made the angle of the effective divergence of the lens, we have $\Delta' = 2\Delta$.

Adopting this rule we find the effective divergence of the lens to be about 5° 9′, which does not differ much from the observed divergence.

Manufacture of dioptric instruments.

The manufacture of the dioptric instruments is not distinguished by any peculiarity which requires special notice, the grinding and polishing being performed by means of powders gradually increasing in fineness, successively applied as in the ordinary process of grinding glass. The union of the several zones which compose an annular lens is effected by means of small slips of thin copper, which having one half passed into a groove in one zone, and the other half into a corresponding groove in the adjoining zone, prevent, in the same manner as a *joggle* in masonry, or a *chock* in carpentry, the one zone from slipping past the other. The pieces are also united by a glue which possesses the important property of being able to resist the action of considerable heat, whilst it is by no means brittle. M. Fresnel intrusted the work of building the first lens to the late M. Soleil, optician to the king of France, to whose zeal and intelligence he bears ample testimony in the *Memoire* in which he describes the invention.

Testing of lenses.

In order to test the figure of the lenses, moulds carefully made may be applied; or the lens being mounted on a stand which permits its being set at any angle, the accuracy of the whole instrument, and of each portion of it, may be separately tested by the form and size of the spectrum which is formed in the principal focus, by permitting the solar rays to fall upon the lens at right angles. When any particular portion is to be tried, the rest of the surface is covered with discs of strong grey paper or pasteboard. Another method may be employed similar to that already described as applicable to reflectors. This method consists in finding whether a small object placed in any point of the axis farther from the lens than the principal focus, has its image refracted accurately to a point on a screen placed in the conjugate focus which is due to that distance. The same principle of testing the instrument is also applied when a person stationed at a given short distance in front of the lens observes whether its whole surface be completely illuminated by a small flame placed in the conjugate focus corresponding to that distance. All that is necessary, therefore, is to determine these distances by means of formulæ which express the relations of the distances of the object and its image. If δ represent the distance of the eye from the lens, ϕ the principal focus, and ϕ' the distance of the conjugate focus corresponding to the observer's distance δ, then we have $\phi' = \frac{\delta\phi}{\delta - \phi}$.

If, again, adopting the same notation, we wish to find the distance at which the image of an object placed at a given distance from the lens greater than that of the principal focus, should be accurately impressed on a screen, we have $\delta = \frac{\phi\phi'}{\phi' - \phi}$

Curved mirrors.

The curved mirrors, as already mentioned, are, strictly speaking, generated by portions of parabolas having their foci coincident with the common flame of the system. In practice, however, they are made portions of a curve surface, ground by the radius of the circle which osculates the given parabola, and passes tangentially through the middle of the chord which subtends the arc of the mirror. These mirrors are plates of glass, silvered on the back, and set in flat cases of sheet brass. They are suspended on a circular frame by screws, which are attached to the backs of the cases, and which afford the means of adjusting them to their true position in the lightroom, so that they may reflect the horizon of the lighthouse to an observer's eye placed in the focus of the system. In order to test the accuracy of the mirrors, recourse may again be had to the formulæ of conjugate foci; thus, if we put r equal to the radius of curvature of the mirror, d equal to the given distance of any object from the mirror, and d' equal to the distance of a moveable screen, which shall receive the true image of the object if the mirror be accurately formed, we shall have for this latter distance $d' = \frac{rd}{2d - r}$.

Power of the annular lenses, cylindric refractors and curved mirrors.

The effect of an annular lens may be estimated at moderate distances to be nearly equal to that of 3000 Argand flames of about an inch diameter; that of a cylindric refractor at about 250; and that of a curved mirror may perhaps on an average be assumed at about 10 Argand flames.

Catadioptric light.

A beautiful apparatus, which has received the name of the *catadioptric* light, from the compound action by which it is characterised, was another of Fresnel's applications of dioptric instruments to the purposes of a lighthouse. This elegant apparatus consists of thirteen rings of glass of various diameters arranged one above another, in an oval form. The five middle rings have an interior diameter of 11·81 inches (30$^{cm.}$) and refract equally over the horizontal plane of the focus the light which they receive from it, and thus operate precisely in the same manner as the dioptric part of the fixed light apparatus. The other rings or prisms, five of which are upper and three lower, are ground and set in such a manner, that they project all the light derived from the focus in a direction parallel to the other rays by *total reflection*. This effect is produced by arranging the prisms, so that the incident rays, after being refracted at the first surface, shall strike the reflecting side of the prism at such an angle, that instead of passing through the prism at that point, they shall be *totally reflected* from it, and after a second refraction emerge from the third side in a direction parallel to those transmitted by the middle or simply refracting rings. When this apparatus is employed to light only a part of the horizon, the rings are discontinued on the side next to the land, and room is thus obtained for using a common fountain lamp; but when the whole horizon is to be illuminated, the apparatus must inclose the flame on every side, so that it has in this case been found necessary to employ the hydrostatic lamp of Thilorier, in which the balance is sulphate of zinc in solution. Fresnel was prevented, by an early death, the consequence of severe application to scientific pursuits, from ever constructing this beautiful instrument; and it was reserved for the present enlightened secretary of the *Commission des Phares* to complete his brother's invention.

The nature of this apparatus will be fully understood by a reference to fig. 1. Plate I. which shews its section and plan. F is the focal point in which the flame is placed, *r*, *r* cylindric refractors, forming by their union a cylinder with a lamp in its axis, and producing a zone of light of equal intensity all round the horizon, and *r′*, *r′* are cylindric refractors having their axes at right angles to those of the refractors *r*, *r*, and revolving around them. These exterior refractors in front of the inner refractors produce, by compound refraction, a beam similar to that resulting from an annular lens. *x*, *x* are catadioptric prismatic rings acting by *total reflection*, and giving out zones of light of equal intensity at every point of the horizon. The dotted lines shew the course traversed by the rays of light which proceed from the lamp and are acted upon by the rings of glass. The catadioptric rings supply the places of the curved mirrors M, M, shewn in Plate II. figs. 3 and 4; and as the reflection from the inner surface of a prism is, theoretically speaking, *total*, and the whole loss of light is merely that which is due to absorption in passing through the glass, and that which takes place at the two surfaces, there must of necessity be a much greater proportion of the incident light transmitted by the catadioptric action than can ever be obtained from the most perfect reflecting surface, the loss from reflection being held to be in no case less than one half of the incident light.

Catadioptric prisms or lights of the first order.

This consideration, together with some other views regarding the greater convenience of the catadioptric apparatus, led Mr. Alan Stevenson to propose to the Commissioners of the Northern Lighthouses, in a report, dated 8th October 1836, that an inquiry should be instituted regarding the practicability of substituting in lights of the first order, a series of catadioptric prisms in the room of the curved mirrors which are at present used in France. Having received authority from the Lighthouse Board, he corresponded with M. Fresnel at Paris, who, in the most liberal manner, furnished him with all the information regarding the steps which he had pursued in reference to the smaller apparatus, and at the same time suggested many important views regarding the larger one.

In the small apparatus of the fourth order, the nearness of the prisms to the flame makes the angle subtended by the first refracting side considerable; and as the curvature of the reflecting side of the prisms depends upon this angle, the excess of the secant, above the radius of the arc, is a notable quantity, and the radius of curvature is proportionally small. But in the prisms of the first order, Mr. A. Stevenson found, that the radius of curvature of the reflecting side is upwards of 24 feet, and that, even when the generating triangles are larger than those of the small apparatus, the excess of the secant over the radius is only about ·0125 inch. Where a flame of great size, like that which illuminates the dioptric apparatus, is used, this curvature may be safely disregarded; and is, indeed, such, that it could not be accurately ground, on account of the great length and unwieldiness of the radius. It is true, that an approximation to the true figure might be made, by giving to the reflecting side the form which would be traced by two tangents to the curve, and thus forming a trapezoidal prism; but the difficulty of such an operation, where so little glass is to be removed, and the increased source of error from the necessity of an additional shifting of the glass on the chucks, seem to be sufficient reasons for rejecting this expedient. It ought also to be recollected, that in this case the tendency of the deviation from the theoretical form, is towards the side of safety, as the error in the path of any ray which it could cause, would throw the light at its emergence from the prism below, and not above the horizon. The prisms may therefore be considered as rings generated by the revolution of isosceles triangles round a vertical axis passing through the focus of the system.

Mr. Edward Sang, F.R.S.E. in an interesting communication on the grinding of glass, which was lately read before the Society of Arts for Scotland, pointed out the advantage of adopting the highest point of the flame as the focus of the system of reflecting rings. By this arrangement, the light from the upper part of the flame, which would otherwise escape upwards, will be directed to the horizon, whilst the rays from the lower parts of the flame will be usefully directed to illuminate the space between the horizon and the lighthouse.

Arrangement of a paratus in the lighthouse.

All the lights on the dioptric principle, are illuminated by a flame placed in the centre of the apparatus or common focus of the principal lenses and cylindric refractors which are ranged round it. The burner of the lamp varies in its dimensions and its consumption of oil, according to the size of the instruments employed, which also determines what is called the *order* of the light, a name expressive of its *power* and *range*. Above and below the strictly dioptric part of the apparatus of each order, there are also accessary parts, which are generally simply catoptric, and consist of curved mirrors arranged in tiers, one above another, like the leaves of a Venetian blind and placed so as to reflect to the horizon the rays received from the lamp, which is in their common focus. At Corduan, however, and at Planier, near Marseilles, the apparatus above the principal lenses is dia-catoptric, being composed of an union of eight lenses of 19·68 inches (50$^{cm.}$) of focal distance, inclined inwards to the flame, which is in their common focus, and thus forming a frustum of an octagonal pyramid of 50° of inclination. These upper lenses are surmounted by plane mirrors, placed so as to reflect horizontally the beams transmitted by the lenses. In placing these upper lenses, it has been thought advisable to give their axes a horizontal inclination of 7° from that of the great lenses. By this arrangement, the flash of the upper lenses always precedes that of the principal lenses, as already noticed in speaking of the appearance of Corduan light. The use of the accessary apparatus is to collect the rays, which would otherwise pass above and below the main lenses, without contributing to the brilliancy of the light. The nature of the whole apparatus will be more fully understood by referring to the Plates.

Plate II. fig. 1, is a section of a revolving dioptric apparatus of the first order; F is the focal point in which the flame is placed; L, L great annular lenses, forming by their union an octagonal prism, with the lamp in its axis, and projecting in horizontal beams the light which they receive from the focus; L′ L,′ upper lenses, forming by their union a frustum of an octagonal pyramid of 50° of inclination, and having their foci coinciding in the point F. They parallelise the rays of light which pass over the lenses. M, M, plane mirrors, placed above the pyramidal lenses, and so inclined, as to project the beams reflected from them in planes parallel to the horizon; X, X shew the rollers and wheel work which give motion to the lenses; and W is the weight which moves the clock-work of the mechanical lamp H. Plate II. fig. 2, is the plan of the apparatus shewn in fig. 1.

Plate II. fig. 3, shews a section of a fixed dioptric light of the first order. F is the focal point in which the flame is placed; R, R cylindric refractors, forming by their union a prism of thirty-two sides, or a true cylinder, with the lamp in its axis, and producing a zone of light of equal intensity in every point of the horizon; M, M curved mirrors, ranged in tiers above and below the cylindric refractors, and having their foci coinciding in the point F; the effect of the mirrors increases the power of the light, by collecting and transmitting the rays which would otherwise pass above and below them, without increasing the effect of the light; W is the weight which moves the mechanical lamp H. Plate II. fig. 4, is a plan of the fixed apparatus of the first order.

The cylindric form given to the refracting belts of the first order.

Mr. Alan Stevenson having been directed by the Commissioners of the Northern Lighthouses to convert the fixed catoptric light of the Isle of May, into a dioptric light of the first order, proposed, that an attempt should be made to form a true cylindric, instead of a polygonal belt for the refracting part of the apparatus; and this task was successfully completed by Messrs. Cookson of Newcastle. The defect of the polygon lies in the excess of the radius of the circumscribing circle over that of the inscribed circle, which occasions an unequal distribution of light between its angles and the centre of each of its sides; and this fault can only be fully remedied by constructing a cylindric belt, whose generating line is the middle mixtilinear section of an *annular* lens, revolving about its principal focus as a vertical axis. This is, in fact, the only form which can possibly produce an equal diffusion of the incident light over every part of the horizon.

In a report to the Commissioners of the Northern Lights, there is the following description of the refractors constructed for the Isle of May Light. "I at first imagined," says Mr. Alan Stevenson, "that the whole hoop of refractors might be built between two metallic rings, connecting them to each other solely by the means employed in cementing the pieces of the annular lenses; but a little consideration convinced me that this construction would make it necessary to build the zone at the lighthouse itself, and would thus greatly increase the risk of fracture. I was therefore reluctantly induced to divide the whole cylinder into ten arcs, each of which being set in a metallic frame, might be capable of being moved separately. The chance of any error in the figure of the instrument has thus a probability of being confined within narrower limits; whilst the rectification of any defective part becomes at the same time more easy. One other variation from the mode of construction at first contemplated, has been forced upon me by the repeated failures which occurred in attempting to form the middle zone in one piece; and it was at length found necessary to divide this belt by a line passing through the horizontal plane of the focus. This division of the central zone, however, is attended with no appreciable loss of light, as the entire coincidence of the junction of the two pieces with the horizontal plane of the focus, confines the interception of the light to the fine joint at which they are cemented. With the exception of these trifling changes, the idea at first entertained of the construction of this instrument has been realized. An improvement of some importance might also be made upon the arrangement of this apparatus, by giving to the metallic frames which contain the prisms, a rhomboidal,[1] instead of a rectangular form. The junction of the frames being thus inclined from the perpendicular, will not in any azimuth intercept the light throughout the whole height of the refracting belt, but the interception will be confined to a small rhomboidal space, whose area will be inversely proportional to the sine of the angle of inclination; and if the helical joints be formed between the opposite angles of the present rectangular frames, the amount of intercepted light will be absolutely equal in every azimuth."

The change of the light at the Isle of May, from the catoptric to the dioptric system, was generally acknowledged to be an improvement. A committee of the Royal Society of Edinburgh made some observations on the two lights which were exhibited in contrast on the night of the 26th of October 1836, from the town of Dunbar, which is distant about thirteen miles from the lighthouse. Their report, which was drawn up by Professor Forbes, concludes in these words:

"The following conclusions seem to be warranted:

"1. That at a distance of thirteen miles, the mean effect of the new light is very much superior to the mean effect of the old light, (perhaps in the ratio of two to one.)

"2. That at *all* distances, the new light has a prodigious superiority to the old, from the equality of its effects in all azimuths.

"3. That the new light fulfils rigorously the conditions required for the distribution of light to the greatest advantage.

"4. That at distances much exceeding thirteen miles, the new light must still be a very effective one, though to what extent the committee have not observed. The light is understood to be still a good one, when seen from Edinburgh at a distance of about thirty miles."

Orders of the French lights.

The dioptric lights used in France, are divided into four orders, in relation to their power and range; but in regard to their characteristic appearances, this division does not apply, as, in each of the orders, lights of identically the same character may be found, differing only in the distance at which they can be seen, and in the expense of their maintenance. The four orders may be briefly described as follows:—

1*st*. Lights of the first order having an interior radius or focal distance of 36·22 inches, ($92^{\text{cm.}}$) and lighted by a lamp of four concentric wicks, consuming 570[2] gallons of oil per annum.

2*d*. Lights of the second order having an interior radius of 27·55 inches, ($70^{\text{cm.}}$) lighted by a lamp of three concentric wicks, consuming 384 gallons of oil per annum.

3*d*. Lights of the third order, lighted by a lamp of two concentric wicks, consuming 183 gallons of oil per annum. The instruments used in these lights are of two kinds, one having a focal distance of 19·68 inches, ($50^{\text{cm.}}$) and the other of 9·84 inches ($25^{\text{cm.}}$)

4*th*. Lights of the fourth order, or harbour lights, having an internal radius of 5·9 inches (15$^{cm.}$), and lighted by a lamp of one wick, or Argand burner, consuming 48 gallons of oil per annum.

---

[1] "The form could not be exactly rhomboidal, but would be a portion of a flat helix intercepted between two planes, cutting the enveloped cylinder at right angles to its axis."

[2] The experience of two at the Isle of May and Inchkeith, shews that the annual expenditure of spermaceti oil, in lights of the first order, does not exceed 570 gallons.

The four orders, as already hinted above, and explained by M. Fresnel in his observations prefixed to the list of the French lights for 1833, are not intended as distinctions; but are characteristic of the power and range of lights, which render them suitable for different localities on the coast, according to the distance at which they can be seen. This division, therefore, is analogous to that which separates our lights into *sea-lights*, *secondary lights*, and *harbour lights*, terms which are used to designate the power and position, and not the appearance of the lights to which they are applied.

Each of the above orders is susceptible of certain combinations, which produce various appearances, and constitute the distinctions used for dioptric lights; but the following are those which have been actually employed as the most useful in practice:—

The first order contains, 1*st.* Lights producing great flashes, preceded by smaller ones, once in every minute, by the revolution of eight great annular, and eight smaller lenses, as at Corduan; 2*d.* Lights flashing once in every half minute, and composed of sixteen half lenses. These lights may have the subsidiary parts simply catoptric, as at Biarritz, or dia-catoptric, as at Planier; and, 3*d.* Fixed lights, composed of a combination of cylindric pieces, with mirrors ranged in tiers above and below them as at the Isle d'Yeu.

The second order comprises revolving lights with sixteen or twelve lenses, which make flashes every half minute; and fixed lights varied by flashes once in every four minutes, as at Pilier, an effect which is produced by the revolution of exterior cylindrical pieces.

The third order (larger diameter) contains common fixed lights, and fixed lights varied by flashes once in every four minutes, as at Aiguesmortes.

The third order, (smaller diameter,) contains fixed lights, varied by flashes once in three minutes, as at Commerce on the Loire, and common fixed lights, as at Aiguillon, Grave, and Dunkerque.

The fourth order has fixed lights varied by flashes once in every three minutes, and fixed lights of the common kind, as at Pertuis-Breton, and La Coubre. It has been thought necessary to change the term "fixed lights varied by flashes," for "fixed light with short eclipses," because it has been found that, at certain distances, a momentary eclipse precedes the flash.

These distinctions depend upon the periods of revolution, rather than upon the *characteristic appearance* of the light; and therefore seem less calculated to strike the eye of a seaman, than those employed on the coasts of Great Britain and Ireland. In conformity with this system, and in consideration of the great loss of light which results from the application of coloured media, all distinctions based upon colour have been discarded in the French lights.

Comparison of dioptric and catoptric lights.

Having thus fully described the nature of the catoptric and dioptric modes of illuminating light-houses, we shall next proceed to compare the merits of both systems, with a view to determine their eligibility in revolving or in fixed lights.

Revolving lights

Repeated experiments were made at Gulan-hill, which is distant from Edinburgh about fifteen miles, during the winters of 1832 and 1833, under the inspection of the Commissioners of Northern Lights, the result of which was, that the light of one of the great annular lenses used in the revolving lights of the first order, was equal to the united effect of about eight of the large reflectors employed in the revolving lights on the Scotch coast. It may be said, however, that the diacatoptric combination of pyramidal lenses and plane mirrors of Corduan, adds the power of more than two reflectors to the effect of the great lens; but it ought to be remembered that in the French lights, this additional power is used only to lengthen the duration of the flash, and therefore in no degree contributes to render the light visible to the mariner at a greater distance. M. Fresnel found from the smaller divergence of the lens, that the eclipses were too long, and the bright periods of the revolution too short; and he therefore determined to adopt the horizontal inclination of 7° for the upper lenses, with a view to remedy this defect. Assuming, therefore, that it were required to increase the number of reflectors in a revolving light of three sides, so as to render it equal in power to a dioptric revolving light of the first order, it would be necessary to place eight reflectors on each face, so that the greatest number of reflectors required for this purpose may be taken at *twenty-four*. M. Fresnel has stated the expenditure of oil in the great lamp of four concentric wicks at 750 grammes of oil of colza per hour; and it is found by experience at the Isle of May and Inchkeith, that the quantity of spermaceti oil consumed by the great lamp, is equal to that burned by fourteen of the Argand lamps used in the Scotch lights. It therefore follows that, by dioptric means, the consumption of oil necessary for fourteen reflectors, will produce a light as powerful as that which would require the oil of twenty-four reflectors in the catoptric system followed on the coast of Scotland; and consequently, that there is an excess of oil equal to that consumed by ten reflectors, or 400 gallons in the year, against the Scotch system. But in order fully to compare the economy of producing two revolving lights of equal power by these two methods, it will be necessary to take into the calculation the interest of the first outlay in establishing them.

The expense of fitting up a revolving light with twenty-four reflectors, ranged on three faces, may be estimated at L.1298, and the annual maintenance at L.418, 8s. 4d. The fitting up a revolving light with eight lenses, and the dia-catoptric accessary apparatus, may be estimated at L.1263, and the annual maintenance at L.280, 10s. 4d. It therefore follows, that to establish, and afterwards maintain a catoptric light, of the kind called *revolving white*, (as that of Start Point in Orkney, where the frame has only three faces,) so as to be equal in power to the dioptric light of Corduan, an annual outlay of L.137. 18s. more would be required for the reflecting light than for the lens light; whilst for a light of the kind called *revolving red and white*, (as the Bell Rock or Cape Wrath, where the frame has four faces,) thirty-six reflectors would be required to make the light equal in power to that of Corduan; and the catoptric light would in this case cost L.333 more than the dioptric light.

Fixed lights.

We shall now speak of fixed lights, to which the dioptric method is peculiarly adapted. The effect produced by the consumption of a gallon of oil in a fixed light, with twenty-six reflectors, like that formerly exhibited at the Isle of May, may be estimated as follows:—The mean intensity of the light spread over the horizontal sector subtended by one reflector, as measured at each degree by the method of shadows, is equal to that of 174 unassisted Argand burners. If, then, this quantity be multiplied by 360 degrees, we shall obtain an aggregate effect of 62640, which, divided by 1040, the number of gallons burned during a year, by twenty-six reflectors, would give *sixty* Argand flames for the intensity of light maintained throughout the year by the combustion of a gallon of oil. On the other hand, the effect of a dioptric light like that lately established at the Isle of May, may be estimated thus. The mean intensity of the light produced by the joint effect of both the dioptric and catoptric parts of a fixed light apparatus, may be valued at 376 Argand flames, which, multiplied by 360 degrees, gives an aggregate of 135360; and if this quantity be divided by 570, the number of gallons burned by the great lamp in a year, we shall have nearly 237 for the intensity of light produced by the combustion of a gallon of oil. It would thus appear that in fixed lights, the French apparatus produces nearly *four times* more light, by the combustion of the same quantity of oil, than can be obtained by the catoptric mode.

But the great superiority of the dioptric method chiefly rests upon its fulfilling *perfectly* the condition required in a fixed light, by distributing a more intense light *equally* in every point of the horizon. In the event of the whole horizon not requiring to be illuminated, the dioptric light would lose a part of its superiority in economy, and when half the horizon only is lighted, it would be more expensive than the reflected light; but the greater power and more equal distribution of the light, may be considered of so great importance, as far to outweigh any difference of expense. In the latter case, too, an additional power might be given to the light, by placing at the landward side of the lightroom, a spherical mirror with its centre in the focus of the dioptric apparatus. The luminous cone of which such a reflector forms the base, instead of passing off uselessly to the land, would thus be thrown back through the focal point, and finally refracted, so as to contribute to the effect of the light seaward.

The expense of establishing a fixed light composed of twenty-six reflectors, may be estimated at L.950, and the annual maintenance at L.425, 10s.; and the expense of fitting up a fixed light on the dioptric principle is L.1058; and the annual maintenance may be taken at L.267, 6s. 4d. It thus appears that the annual expenditure of the dioptric fixed light is L.158, 3s. 8d. less than that of a fixed light composed of twenty-six reflectors; and the light given out is *four times* more powerful, and it is at the same time more equally diffused over the horizon.

The comparative views already given of the catoptric and dioptric modes of illuminating lighthouses, demonstrate that the latter produces more powerful lights by the combustion of the same quantity of oil; while it is obvious that the catoptric system insures a more certain exhibition of the light, from the fountain lamps being less liable to derangement than the mechanical lamps used in dioptric lights. The balance, therefore, of real advantages or disadvantages, and consequently the propriety of finally adopting one or other, involves a mixed question, not susceptible of very absolute solution, and leaving room for different decisions, according to the value which may be set upon obtaining a cheaper and better light, on the one hand, as contrasted with less certainty in its exhibition, on the other. A few general considerations, which may serve briefly to recapitulate the arguments for and against the two systems, may not be out of place. And, first, regarding the fitness of dioptric instruments for revolving lights, it may be observed, that, from the details above given, it appears,

Recapitulation.

Revolving lights.

1*st.* That by placing eight reflectors on each face of a revolving frame, a light may be obtained as brilliant as that derived from the great annular lens; and that in the case of a frame of three sides, the excess of expense by the reflecting mode, would be L.137, 18s.; and in the case of a frame of four sides, the excess would amount to L.333.

2*d.* The diverging property of the lens being less than that of the reflector, it becomes difficult to produce, by lenses, the appearance which characterises catoptric revolving lights, which are already so well known to British mariners; and any change which might affect their appearance, would involve many grave practical objections.

3*d.* The uncertainty of the management of the lamp renders it more difficult to maintain the revolving dioptric lights without fear of extinction, an accident which has several times occurred at Corduan and other French lighthouses.

4*th.* The extinction of one lamp in a revolving catoptric light is not only less probable, but leads to much less serious consequences than the extinction of the single lamp in a dioptric light; because, in the first case, the evil is limited to diminishing the power of *one face* by an *eighth* part; whilst, in the second, the *whole horizon is totally deprived of light.* The extinction of a lamp, therefore, in a dioptric light, leads to evils which may be considered *infinitely great* in comparison with the consequences which attend the same accident in a catoptric light.

Fixed lights.

In comparing the fixed dioptric, and the fixed catoptric apparatus, the results may be ranged under the following heads:

1*st.* It is impossible, by means of any practical combination of parabolic reflectors, to distribute round the horizon a zone of light of exactly *equal intensity;* while this may be easily effected, by dioptric means, in the manner already described. In other words, the qualities required in fixed lights cannot be so *perfectly* obtained by reflectors as by refractors.

2*d.* The light produced by burning one gallon of oil in Argand lamps, with reflectors, has only about *one-fourth* of the intensity of that produced by burning the same quantity in the dioptric apparatus; and the annual expenditure is L.158, 3s. 8d. less for the dioptric than for the catoptric light.

3*d.* The characteristic appearance of the fixed reflecting light would not be changed by the adoption of the dioptric method, although its increased intensity would render it visible at a greater distance.

4*th.* From the equal distribution of the rays, the dioptric light would be observed at equal distances in every point of the horizon; an effect which cannot be fully attained by any practicable combination of parabolic reflectors.

5*th.* The inconveniences arising from the uncertainty which attends the use of the mechanical lamp, are not so much felt in a fixed as in a revolving light, because the less complex nature of the apparatus admits of easier access to it, in case of accident. In those situations, too, where the horizon is not illuminated all round, the mechanical lamp may perhaps be supplanted by a large fountain lamp of four concentric wicks, the use of which would, in a great measure, remove the objection of uncertainty in the exhibition of the light.

6*th.* But the extinction of a lamp in a catoptric light, leaves only one-26th part of the horizon without the benefit of the light, and the chance of accident arising to vessels from it may, therefore, be considered as incalculably less than the danger resulting from the extinction of the single lamp of the dioptric light, which deprives the whole horizon of light.

7*th.* There may also, in certain situations, be some danger arising from the irregularity in the distances at which the same fixed catoptric light may be seen in the different points of the horizon. This defect, of course, does not exist in the dioptric light.

Introduction and progress of Fresnel's system in Britain and other countries.

There can be little doubt, that the more fully the system of Fresnel is understood, the more certainly will it take the place of all other systems of illumination for lighthouses, at least, in those countries where this important branch of administration is conducted with the care and solicitude which it deserves. To the Dutch belongs the honour of having first embraced the system of Fresnel in their lights. The Commissioners of the Northern Lights followed in the train of improvement, and in 1834, sent Mr. Alan Stevenson on a mission to Paris, with full power to take such steps for acquiring a perfect knowledge of the dioptric system, and forming an opinion on its merits, as he should find necessary. The singular liberality with which he was received by M. Léonor Fresnel, brother of the late illustrious inventor of the system, and his successor as the Secretary of the Lighthouse Commission of France, afforded Mr. A. Stevenson the means of making such a report on his return, as induced the Commissioners to authorise him to remove the reflecting apparatus of the revolving light at Inchkeith, and substitute dioptric instruments in its place. This change was completed, and the light exhibited on the evening of 1st October 1835, and so great was the satisfaction which the change produced, that the Commissioners immediately instructed Mr. Stevenson to make a similar change at the fixed light of the Isle of May, where the new light was exhibited on the 22d September 1836. The Trinity House of London followed next in adopting the improved system, and employed Mr. A. Stevenson to superintend the construction of a revolving dioptric light of the first order, which was afterwards erected at the Start Point in Devonshire. Other countries begin to shew symptoms of interest in this important change; and America, it is believed, is likely soon to adopt active measures for the improvement of her lighthouses. Fresnel, who is already classed with the greatest of those inventive minds which extend the boundaries of human knowledge, will thus, at the same time, receive a place amongst those benefactors of the species who have consecrated their genius to the common good of mankind; and, wherever maritime intercourse prevails, the solid advantages which his labours have procured, will be felt and acknowledged.

Fuel of lighthouses.

The fuel commonly adopted in the best lighthouses of Great Britain, is spermaceti oil, which is obtained from the South Sea whale, *(Physeter macrocephalus)*; and in France the oil generally burned is expressed from the seed of a species of wild cabbage, *(Brassica oleracea colza)*, and is called *huile de colza*. It appears from some experiments made by M. Léonor Fresnel at Paris, in which he compared the intensity of the light produced by the combustion of equal parts of this oil and the spermaceti oil used in England, of which specimens had been sent to him by the Trinity House of London, that there is but little difference. This conclusion differs somewhat from the result of the trials at the Isle of May and Inchkeith, where flames of similar dimensions to those produced from the colza oil are obtained by the combustion of nearly one-fourth less spermaceti oil. In the lights on the shores of the Mediterranean, olive oil is chiefly used; but the light obtained from it is feeble compared with that of spermaceti or colza oil.

Gas.

In a few lighthouses which are near towns, the gas of pit coal has been used; and there are certain advantages, more especially in dioptric lights, where there is only one large central flame, which would render the use of gas desirable. The form of the flame, which is an object of considerable importance, would thus be rendered less variable, and could be more easily regulated, and the inconvenience of the clock-work of the lamp would be wholly avoided. But it is obvious, that gas is by no means suitable for the majority of lighthouses, their distant situation and generally difficult access, rendering the transport of large quantities of coal expensive and uncertain; whilst in many of them there is no means of erecting the apparatus necessary for manufacturing gas. There are other considerations which must induce us to pause before adopting gas as the fuel of lighthouses; for, however much the risk of accident may be diminished in the present day, it still forms a question, which ought not to be hastily decided, how far we should be justified in running even the most remote risk of explosion in establishments such as lighthouses, whose sudden failure might involve consequences of the most fatal description, and whose situation is often such, that their re-establishment must be a work of great expense and time. Gas is, besides, far from being suitable in catoptric lights, to which, where the frame is moveable, as in revolving lights, it could not be applied.

Drummond and Voltaic lights

The application of the Drummond and Voltaic lights to lighthouse purposes is, owing to their prodigious intensity, a very desirable consummation; but it is surrounded by so many practical difficulties, that it may safely, in the present state of our knowledge, be pronounced unattainable. The uncertainty which attends the exhibition of both these lights, is of itself a sufficient reason for coming to this conclusion. But other reasons unhappily are not wanting. The smallness of the flame renders those lights wholly inapplicable to dioptric instruments, which require a great body of flame in order to produce a degree of divergence sufficient to render the duration of the flash in revolving lights long enough to answer the purpose of the mariner. M. Fresnel made some experiments on the application of the Drummond light to dioptric instruments, which completely demonstrate their unfitness for this combination. He found that the light obtained by placing it in the focus of a great annular lens, was much more intense than that produced by the great lamp and lens of Corduan; but the divergence did not exceed 30′; so that, in a revolution like that of Corduan, the flashes would last only $1\frac{1}{3}$ second, and would not, therefore, be seen in such a manner as to suit the practical purposes of a revolving light. The great cylindric refractor used in fixed lights of the first order, was also tried with the Drummond light in its focus; but it gave coloured spectra at the top and bottom, and only a small bar of white light was transmitted from the centre of the instrument. The same deficiency of divergence completely unfits the combination of the Drummond light with the reflector for the purposes of a fixed light, and even if this cause did not operate against its application in revolving lights on the catoptric plan, the supply of the gases, which is attended with almost insurmountable difficulties, would, in any case, render the maintenance of the light precarious and uncertain in the last degree.

Mr. Gurney's lamp.

In 1835, Mr. Gurney proposed the combination of streams of oxygen with the flame of oil or wax, in order to obtain a powerful light of sufficient size to produce the divergence required for the illumination of lighthouses. The Trinity House of London entertained the proposal, and have since been engaged in making experiments on this important subject; and their efforts, it is believed, have been attended with a measure of success which holds out a reasonable prospect of this lamp being finally used in lighthouses. In applying this light to reflectors, it is intended to use three small flames, each about three-eighths of an inch in diameter, which produce, it is said, an effect equal to that of ten common Argand lamps. The burner intended for lenses has seventeen films of flame, and is said to possess six times the power of the Fresnel lamp. The light is considered cheaper than that which is obtained by the combustion of oil in atmospheric air.

We shall conclude by a brief account of the lights of various countries, and the mode of management that is adopted, so far as we have the means of speaking with certainty on this subject.

Trinity House of London.

The lights on the coast of England are under the management of the Corporation of Trinity House of Deptford Strond. Before the reign of Henry VIII., the Trinity House appears to have been merely a fraternity of seamen, and it was not till the sixth year of Henry's reign that it was incorporated by royal charter. Elizabeth afterwards granted the Trinity House certain privileges of ballastage, beaconage, and buoyage, and empowered them to erect and preserve "beacons and signs for the sea." It does not appear, however, that this body specially undertook the erection of lighthouses, till about the year 1676. Before that time it was common to grant letters patent in favour of the proprietors of the lands adjoining the site of a lighthouse, empowering them to erect a lighthouse, and to levy certain duties on shipping for its maintenance. In some cases the patentee was bound to pay an annual sum to the Trinity House towards the support of their charities; but in other cases, he was quite independent. The Trinity House have, in numerous instances, entered into new arrangements with the lessees at the expiry of their leases; but it is now the practice of this board to erect and maintain lighthouses on the coast, without the intervention of any arrangement of the nature of a lease; and the result, as might be expected, has been very favourable to the interests of the public. The lights, which were formerly maintained by lessees, whose interests, in some cases, led them to adopt every saving, without regard to the efficiency of the light, are now maintained in a manner worthy of the country to which they belong. This condemnation of the manner in which the lessees of some of the lights discharged their obligations, by no means applies indiscriminately to all of them; for there were several honourable exceptions. In 1834, the court of the corporation of Trinity House consisted of one master, four wardens, eight assistants, and eighteen elder brothers. Of these, eleven are in the honorary line of the brotherhood, and twenty-one are chosen from the merchant service. There are also younger brothers, whose number is unlimited, and who are elected by the elder brothers. The elder brothers are self-elected from the list of younger brothers. The business is managed by seven committees, who separately superintend the treasury and accounts, the examination of and granting certificates to masters in the navy and pilots, the supervision of ballastage in the Thames, the lighthouses, the collection of the dues, the pensioners and the management of the house affairs. In each of these committees a majority constitutes a quorum.

The rate of dues chargeable by the Trinity House before the passing of the last act in 1836, varied from 1-6th of a penny to one penny per ton on each light passed; and it appears from the Parliamentary Report of 1834, that in 1832, the nett amount of revenue was L.77,371, and the expense of maintaining the lights was L.36,904, leaving a surplus of L.40,467. This surplus is partly expended in the extensive charities which are distributed by the Corporation, to the annual amount of L.35,000, and partly in the erection of new lighthouses, and the maintenance of the general establishment.

Lights of England.

The public lights in England, including Heligoland, are 71 in number, and may be arranged in the following classes:—

1st, Those belonging to, and under the management of, the corporation of the Trinity House of Deptford Strond, in number............	55 lights.
2d, Those in the charge of individuals, under lease from the Trinity House, and having different periods to run, viz. the Longships, Smalls, and Mumbles, in number..................................	3 „
3d, Those let by the crown to individuals for a period of years, on leases renewed since 1822, viz. Harwich, 2; Dungeness, 1; Wintertonness and Oxfordness, 3; and Hunstanton Cliff, 1; in number..	7 „
4th, Lights held originally under patents, subsequently sanctioned by acts of Parliament, and now in the hands of proprietors, viz. the Spurn, Tynemouth Castle and Skerries, in number......	4 „
5th, One light at Heligoland.......................	1 „
6th, One floating light at Benbridge Lodge...	1 „
Total number of public general lights in England,....................................	71 „

Lights of Scotland.

The lights in Scotland may be divided into public and local or harbour lights. The public lights are under the management of a board denominated "Commissioners of Northern Lights." The Board was incorporated in 1786, by the 38th Geo. III. c. 58, and the Commissioners hold their office at the board by virtue of the public situations they fill. The Act of the 26th Geo. III. c. 101, gives authority to erect lighthouses and to collect duties.

The commissioners, twenty-five in number, are the Lord Advocate and the Solicitor-General for Scotland; the provosts of Edinburgh, Glasgow, Aberdeen, Inverness, and Campbeltown; the first bailies of Edinburgh and Glasgow; the sheriffs of the counties of Edinburgh, Lanark, Renfrew, Bute, Argyll, Inverness, Ross, Orkney, Caithness, Aberdeen, Ayr, Fife, Forfar, Wigton, Sutherland, and Kincardine, which are maritime counties or shires. The services of the commissioners are entirely gratuitous; there are two or three general meetings annually, and the general business is conducted by committees, whose meetings take place as occasion requires. A committee of the board was appointed at the time the Bell-Rock lighthouse was erected, which has been continued ever since, and to which all general business is referred; special committees have also been appointed for particular objects, as for accounts, stores, experiments on lenses, light-duties, visitation of lighthouses, special repairs and new works; and there is besides a sub-committee on each lighthouse. No public lights on the Scotch coast are in the hands of private individuals; and all the light-dues collected from the general shipping in Scotland, are received by the Commissioners of Northern Lighthouses, for public use. In the year 1641, a patent for the erection of a private light in the island of May, was ratified in the Scottish Parliament; and this is supposed to have been the earliest sea-light on the shores of Scotland. In 1814, the Commissioners purchased the Island from the Duke of Portland for L.60,000, and erected a new lighthouse there. There are now 25 land-lights under the charge of the Commissioners, for which light-dues are levied from the shipping generally; and there are 28 local or harbour lights under the management of trustees and corporations, maintained by dues levied on the trade of the respective ports where the lights are situated, and on vessels resorting to them. Some of these lights are established by act of Parliament, as those of Cumbrae, Clough, and Toward, under the 29th of Geo. III. c. 20. Others, as those of Leith and Dundee, are secured, by ancient charters, to the fraternities of the ports; and others, as those of Montrose and Arbroath, were erected and are maintained, by the ship-owners and merchants of the ports.

Before the passing of the Act 6th and 7th of William IV. there was no separate charge for each of the lights under the management of the Commissioners of the Northern Lights; but each vessel paid a fixed sum according to the limits within which she came. The rates were as follows:—For every British ship or decked vessel sailing within the limits of the light of the island of May, viz. between the Castle of Dunnottar on the north, and St. Abb's Head on the south, 2½d. per ton; and for foreign vessels sailing within these limits, 5d. per ton. For every British ship or decked vessel liable to dues without these limits, 2d. per ton; and for foreign vessels, 4d. per ton. Vessels sailing to or from any place between Holyhead and Howth Head, both inclusive, on the north, paid ¼d. per ton for each of the three lights in the Isle and Calf of Man; and foreign ships ½d. per ton; but if they had paid the other northern duties, they were exempted from the charge for these lights. The rates were levied on the registered tonnage of all vessels passing any of the lighthouses, whether loaded or in ballast, outwards or homewards bound, on a foreign voyage, or sailing coastways; and it appears from the Parliamentary Report of 1834, that the revenue of the Commissioners was L.36,283. Since the passing of the act 6th and 7th of William IV. cap. 79, in 1836, however, the rates of the duties, and the mode of levying them, have been completely altered, and in some degree assimilated to the system pursued by the Trinity House, so that a certain duty is now paid for every light that is passed.

Lights of Ireland.

The lights of Ireland have had frequent changes in regard to superintendance, and they were finally placed under "The Corporation for Preserving and Improving the Port of Dublin," by the act 50th Geo. III. c. 35. The powers of the corporation, which is generally named the Ballast Board, have received various alterations by subsequent acts. It consists of 23 members, viz. the lord mayor and sheriffs of Dublin, three aldermen chosen by the board of aldermen from their own body, and 17 members appointed in the first instance by the act of incorporation, and who are on all future vacancies empowered to elect new members. The board devotes one day a-week to the business of the lighthouses.

There are thirty-six land lights, and three floating lights, supported by the Ballast board in Ireland. Of these land lights, twenty-six are public lights, and ten are local or harbour lights. There are besides five other harbour lights on the coast, supported by the trustees of the respective harbours.

It appears from the Parliamentary Report of 1834, that the revenue derived from collection of lighthouse dues in Ireland during the year 1833, was L.42,060 The mode of charging the light dues was formerly as follows:—Any British or Irish vessel and foreign privileged vessels on oversea voyages, paid one farthing per ton for every light they passed in the track of their voyage; foreign ships not privileged paid one halfpenny per ton. Coasters, loaded, paid one farthing per ton for every lighthouse or floating light they passed; if in ballast, one eighth of a penny only per ton; and rules were laid down as to the number of lights to be paid for by vessels navigating St. George's Channel, to or from the Atlantic Ocean; as well as for passing through the northern channel bound to the northward, and returning; for going down St. George's Channel, to the eastward; and for sailing from a western port of Ireland to the eastward, without entering St. George's Channel.

New act of 6th and 7th William IV. cap. 79.

The last act of Parliament regarding lighthouses, was the result of a report of a select committee on lighthouses, which was moved for by Mr. Joseph Hume, M.P. and which sat in 1834. The act was passed in 1836. The chief alterations upon the former state of the Boards in which the management of the lights is vested, are the following. The duties levied under all former acts were repealed; and it was enacted, that every British vessel, and every privileged foreign vessel, should pay the toll of one halfpenny, for every time of passing or deriving advantage from any light, with exception of the Bell-rock, for which one penny per ton is the toll. Every foreign vessel not privileged, must pay double toll. The only exemptions from the payment of duties, are in favour of the King's vessels, those of the Trinity House, and all vessels going in ballast, or engaged in the herring fisheries. Power was also given to the Commissioners of the Northern Lighthouses, to erect beacons, and moor buoys; and the harbour lights on the Scotch coast were placed under their controul. The Act confers upon the Trinity House, the power of entering any lighthouse under the charge of the other boards, to inspect their condition, and gives them a controul as to the erection of new lighthouses, or the alteration of those already existing, both in Scotland and Ireland. But in the event of a difference of opinion arising between the Trinity House and either of the two other Boards, appeal may be made to the Privy Council. The Act further provides that an account of the receipt of all money, and a report of all alterations made during the preceding year, should be annually laid before each House of Parliament, one month after its meeting.

Expense of lights of Great Britain.

The average expense of maintaining a land light in Great Britain, is found to be about L.500, and that of a floating light about L.1200.

French lights.

The French lights, of which there are upwards of 100, including about 60 harbour lights, are managed by a particular section of the *Direction Génerale des Ponts et Chaussées*, which is called the *Commission des Phares;* and more than half of the lights are on the dioptric principle of Fresnel.

By an imperial decree of 7th March 1806, the lighthouses and beacons were placed under the charge of the Minister of the Interior; before which time they had been under the immediate direction of the Administration of Roads and Bridges. This decree required that the establishment of every new beacon or light, should proceed upon the joint recommendation of the Ministers of the Marine and the Interior, and gave rise, in 1811, to the institution of the *Commission des Phares*, the members of which, with the exception of the secretary, who is also engineer-in-chief, act without any special remuneration, and in consequence of their holding other official situations. At the time of its first constitution, it appears by the report of Admiral de Rossel, that this Commission consisted of the following gentlemen, viz. Baron Becquey, councillor of state, director-general of roads and bridges, President of the Commission; M. Halgan, rear-admiral, and councillor of state; M. De Prony, inspector-general of roads and bridges; M. Arago, astronomer-royal, member of the Institute; M. Sganzin, inspector-general of roads and bridges; M. Rolland, inspector-general of naval works; M. Tarbe De Vauxclairs, inspector-general of roads and bridges; M. Mathieu, member of the Institute; and M. Augustin Fresnel, member of the Institute, secretary and engineer-in-chief to the Commission.

All the more important plans for the improvement and establishment of lights, are submitted to this Commission; but the plans for new lighthouse towers are only discussed in reference to their fitness for the lights; and every question regarding the buildings or estimates, is submitted to the General Council of the Administration of Roads and Bridges, for their final approbation. The Engineer of the Commission prepares all the plans, and directs the fitting up of the optical apparatus and the lanterns, and sends to the engineers of the departments, the schemes for new lights, that they may make the plans for the necessary buildings connected with them. He also inspects the lights on the coast, and is responsible for their efficient condition. In the discharge of these duties, he is assisted by three *conducteurs* of works, who generally see the apparatus fitted up, and attend to the due performance of the light-room duty.

As soon as a new light is ready, the Administration causes advertisements to be made in the most extensively circulated journals of Paris, containing a notice to mariners regarding its position, appearance, and time of exhibition. This notice is also circulated in every French port by means of placards, which are affixed by the maritime authorities, and generally appear about three months before the exhibition of the light. By a late decree, too, of the Director-general of roads and bridges, the Engineer publishes every year a summary description of all the lights on the coast of France.

Other European lights.

The other lights of Europe are, with the exceptions already mentioned, on the catoptric principle. The writer of this article has seen the greater number of the lights along the coast, between St. Petersburgh and the Spanish frontier; and so far as he has been able to learn, their management is generally vested in some department of the executive government.

American lights.

The Americans have been very active in the establishment of lighthouses. There are upwards of two hundred land lights along the coast of the United States, and twenty-eight floating lights. Their management is entrusted to a board called the General Lighthouse Establishment, which appears to have been regularly organised so early as the year 1791. The total expenditure connected with the Lighthouse Establishment in the year 1837, was about L.71,352; a sum which includes about L.7000 for the maintenance of upwards of 600 buoys and beacons, which are also under the care of the Lighthouse Establishment. The Fifth Auditor of the Treasury is the chief officer of the lighthouse board.

The apparatus is on the catoptric principle; but the reflectors, which are illuminated by means of Argand lamps, are of polished tin-plate, and of small dimensions. The light is from spermaceti oil, the produce of the American South Sea fishery; but experiments have lately been made upon oil produced from cotton-seed; and there is some probability that this oil will be universally employed in the lighthouses of America.

General questions regarding lighthouses.

Distinction and distribution of lights.

There are many questions of much interest regarding Lighthouses, which appear to open an extensive field of inquiry; and it may be doubted whether some of them have received that degree of consideration to which their importance entitles them. Amongst these we may rank the numerous questions which may be raised regarding the most effective kind of distinctions for lights. Those distinctions may be naturally expected to be the most effective which strike an observer by their *appearance* alone. Thus a red and white light, a revolving and a fixed light, offer *appearances* which are calculated to produce upon the observer a stronger sense of their difference, than the same observer would receive from lights whose sole difference lies in their revolutions being performed in greater or less intervals of time. On the other hand, the distinctions derived from time, if the intervals on which they depend do not approach too closely to each other, appear to afford very suitable means for characterising lights; and the number of distinctions which may be founded upon time alone are pretty numerous. Coloured media have the great disadvantage of absorbing light, and the only colour which has hitherto been found useful in practice is red, all others, at even moderate distances, serving merely to enfeeble without characterising lights. In the system of Fresnel, as already explained, all the distinctions are based upon time alone. Mr. Robert Stevenson, the engineer of the Northern Lighthouses, has invented two distinctions, which, although they are produced by variations of the time, possess characteristic *appearances*, sufficiently marked to enable an observer to distinguish a light without counting time. The one is called a *flashing* light, in which the flashes and eclipses succeed each other so rapidly, as to give the appearance of a succession of brilliant scintillations; and the other has been called *intermittent*, from its consisting of a fixed light, which is suddenly and totally eclipsed, and again as suddenly revealed to view. The effect of this light is entirely different from that of any revolving light, both from the great inequality of the intervals of light and darkness, and also from the contrast which is produced by its sudden disappearance and reappearance, which is completely different from the gradual diminution and increase of the light in revolving lights, more especially in those on the catoptric principle. The great and still increasing number of lights renders the means of distinguishing them one of the most important considerations connected with lighthouses.

Arrangement of lights on the coast

Not less important, and very nearly allied to the subject of distinction, is that of the arrangement of lights on a line of coast. The choice of the most suitable places and the assigning to each the characteristic appearances which are most likely to distinguish it from all the neighbouring lights, are points requiring much consideration; and it ought never to be forgotten, that the indiscriminate erection of lighthouses soon leads to confusion and that the needless exhibition of a light, by involving the loss of a distinction, may afterwards prove inconvenient in the case of some future light, which time and the growing wants of trade, may call for on the same line of coast. To enter at length upon this topic, or even to lay down the general principles which ought to regulate the distribution of lights, would exceed the limits of this article; but in connection with this it may be observed, that the superintendance of lighthouses should be committed to one general body, and ought not to be left to local trusts, whose operations are too often conducted on narrow principles, without reference to general interests. The inconveniences arising from interference between the distinctions of the lights under one trust, and those of the lights under another, are thereby avoided; and the full advantage is obtained of the means of distinction at the disposal of both.

Height of tower.

Another important general inquiry, is that regarding the most advantageous height for lighthouses; but this subject is so extensive, and embraces the consideration of so many circumstances, that we can only glance at the chief elements of the question. The distance at which lights should be seen, depends very much upon their position in relation to the dangers of the coast; those which are outposts beyond the danger, require a less extensive range than those which, from unavoidable causes, are situated landward of the dangers which they are intended to point out. Upon this circumstance chiefly depends the height to which a lighthouse tower should be carried; but in many climates, the fogs by which the upper and lower regions of the atmosphere are obscured, introduce elements into the question, which, it is to be feared, must baffle all general rules.

The following works may be consulted on the subject of lighthouses: Smeaton's Narrative of the Eddystone Lighthouse. Lond. 1793. Stevenson's Account of the Bell-Rock Lighthouse. Edinburgh, 1824. (B. I.)

Sea-Plants are those vegetables that grow in salt-water, within the shores of the sea. The old botanists divided these into three classes. The first class, according to their arrangement, contained the *algæ*, the *fuci*, the *sea-mosses* or *confervas*, and the different species of sponges. The second contained substances of a hard texture, like stone or horn, which seem to have been of the same nature with what we call *zoophyta*, with this difference, that we refer sponges to this class, and not to the first. The third class is the same with our *lithophyta*, comprehending corals, madrepores, &c. It is now well known that the genera belonging to the second and third of these classes, and even some referred to the first, are not vegetables, but animals, or the productions of animals. Sea-plants, then, properly speaking, belong to the class of cryptogamia, and the order of algæ; and, according to Bomare, are all comprehended under the genus fucus. We may also add several species of the ulva and conferva, and the sargazo. The fuci and marine ulvæ are immersed in the sea, are sessile, and without root. The marine confervæ are either sessile or floating. The sargazo grows beyond soundings.

Sea-Serpent, a monstrous creature, said to inhabit the northern seas, about Greenland and the coasts of Norway. "In 1756," says Guthrie, "one of them was shot by a master of a ship. Its head resembled that of a horse; the mouth was large and black, as were the eyes, a white mane hanging from its neck. It floated on the surface of the water, and held its head at least two feet out of the sea. Between the head and neck were seven or eight folds, which were very thick; and the length of this snake was more than a hundred yards, some say fathoms. They have a remarkable aversion to the smell of castor; for which reason, ship, boat, and bark masters provide themselves with quantities of that drug, to prevent being overset, the serpent's olfactory nerves being remarkably exquisite. The particularities related of this animal would be incredible, were they not attested upon oath. Egede, a very reputable author, says, that on the 6th of July 1734, a large and frightful sea-monster raised itself so high out of the water, that its head reached above the main-top-mast of the ship; that it had a long sharp snout, broad paws, and spouted water like a whale; that the body seemed to be covered with scales; the skin was uneven and wrinkled, and the lower part was formed like a snake. The body of this monster is said to be as thick as a hogshead; his skin is variegated like a tortoise-shell; and his excrement, which floats upon the surface of the water, is corrosive." No man of sound judgment, however, would think these recitals sufficient to establish the existence of such monsters.

Sea-Sickness, a disorder incident to most persons on their first going to sea, and occasioned by the agitation of the vessel. This disorder has not been much treated of, although it is very irksome and distressing to the patient during its continuance. It appears to be a spasmodic affection of the stomach, occasioned by the alternate pressure and recession of its contents against its lower internal surface, according as the rise and fall of the ship oppose the action of gravity.

Many methods of preventing, or at least mitigating, this disorder, have been recommended, of which the most efficacious appear to be the following: Not to go on board immediately after eating, and not to eat, when on board, any large quantity at a time; to lie down the moment the symptoms are felt, and to remain in the horizontal position till they are removed; to keep much upon deck, even when the weather is stormy, as the sea-breeze is not so apt to affect the stomach as the impure air of the cabin, rendered so for want of proper circulation; and not to watch the motion of the waves, particularly when strongly agitated with tempest.

Sea-Weed, or *Alga marina*, is commonly used as a manure on the sea-coast, where it can be procured in abundance. The best sort grows on rocks, and is that from which kelp is made. The next to this is called the *peasy sea-weed;* and the worst is that with a long stalk.

SEADOWLY, a port of Northern Hindustan, in the territories of the Nepaul rajah district of Mocwanpoor. To this port the British forces penetrated in 1767, and took it; but were obliged to retreat, from the pestilential effects of the climate.

SEAFORD, a town on the sea-shore, in the hundred of Flexborough and rape of Pewensey, in the county of Sussex, sixty-three miles from London. It was in former times much more extensive than it is at present. It is now a mere fishing and bathing place. It is a corporate town, with a bailiff and twelve jurats, and returned two members to the House of Commons till the year 1832. The population amounted in 1821 to 1047, and in 1831 to 1098.

SEAL, a stone, piece of metal, or other matter, usually either round or oval, on which are engraven the arms or device of some prince, state, community, magistrate, or private person, often with a legend or inscription.

The use of seals, as a mark of authenticity to letters and other instruments in writing, is extremely ancient. We read of it among the Jews and Persians in the earliest and most sacred records of history; and in the book of Jeremiah there is a very remarkable instance, not only of attestation by seal, but also of the other usual formalities attending a Jewish purchase. In the civil law, also, seals were the evidences of truth, and were required, on the part of the witnesses at least, at the attestation of every testament. But in the times of our Saxon ancestors they were not much in use in England; for though Sir Edward Coke relies on an instance of King Edwyn's making use of a seal about a hundred years before the Conquest, yet it does not follow that this was the usage among the whole nation; and perhaps the charter he mentions may be of doubtful authority, from this very circumstance of its being sealed, since we are assured by all our ancient historians that sealing was not then in common use. The method of the Saxons was, for such as could write to subscribe their names, and, whether they could write or not, to affix the sign of the cross; which custom our illiterate vulgar for the most part observe, by signing a cross for their mark when unable to write their names. And indeed this inability to write, and therefore making a cross in its stead, is honestly avowed by Cædwalla, a Saxon king, at the end of one of his charters. In like manner, and for the same insurmountable reason, the Normans, a brave but illiterate nation, at their first settlement in France used the practice of sealing only, without writing their names; and this custom continued when learning made its way among them, though the reason for doing it had ceased; and hence the charter of Edward the Confessor, to Westminster Abbey, himself being brought up in Normandy, was witnessed only by his seal, and is generally thought to be the oldest sealed charter of any authenticity in England. At the Conquest the Norman lords brought over into this kingdom their own fashions, and introduced waxen seals only, instead of the English method of writing their names, and signing with the sign of the cross. The impressions of these seals were sometimes a knight on horseback, sometimes other devices; but coats of arms were not introduced into seals, nor indeed used at all, till about the reign of Richard I. who, it is said by some, brought them from the crusade in the Holy Land, where they were first invented and painted on the shields of the knights, to distinguish the variety of persons of every Christian nation who resorted thither.

This neglect of signing, and resting only upon the authenticity of seals, remained in Scotland till the year 1540, when a statute was enacted ordering subscription for the purpose of authenticating deeds and writs.

SEAMANSHIP.[1]

Definition.

By this word we express that noble art, or, more properly, the qualifications which enable a man to exercise the noble art of working a ship. A SEAMAN, in the language of the profession, is not merely a mariner or labourer on board a ship, but a man who understands the structure of this wonderful machine, and every subordinate part of its mechanism, so as to enable him to employ it to the best advantage for pushing her forward in a particular direction, and for avoiding the numberless dangers to which she is exposed by the violence of the winds and waves. He also knows what courses can be held by the ship, according to the wind that blows, and what cannot, and which of these is most conducive to her progress in her intended voyage; and he must be able to perform every part of the necessary operation with his own hands. As the seamen express it, he must be able "to hand, reef, and steer."

Importance and difficulty of the art;

We are justified in calling it a *noble art*, not only by its importance, which it is quite needless to amplify or embellish, but by its immense extent and difficulty, and the prodigious number and variety of principles on which it is founded, all of which must be possessed in such a manner that they shall offer themselves without reflection in an instant, otherwise the pretended seaman is but a lubber, and cannot be trusted on his watch.

The art is practised by persons without what we call *education*, and in the humbler walks of life, and therefore it suffers in the estimation of the careless spectator. It is thought little of, because little attention is paid to it. But if multiplicity, variety, and intricacy of principles, and a systematic knowledge of these principles, entitle any art to the appellation of *scientific* and *liberal*, seamanship claims these epithets in an eminent degree. We are amused with the pedantry of the seaman, which appears in his whole language. Indeed it is the only pedantry that amuses. A scholar, a soldier, a lawyer, nay, even the elegant courtier, would disgust us, were he to make the thousandth part of the allusions to his profession that is well received from the jolly seaman; and we do the seaman no more than justice. His profession *must* engross his whole mind, otherwise he can never learn it. He possesses a prodigious deal of knowledge; but the honest tar cannot tell what he knows, or rather what he feels, for his science is really at his finger ends. We can say with confidence, that if a person of education, versed in mechanics, and acquainted with the structure of a ship, were to observe with attention the movements which are made on board a first or second rate ship of war during a shifting storm, under the direction of an intelligent officer, he would be rapt in admiration.

What a pity it is that an art so important, so difficult, and so intimately connected with the invariable laws of mechanical nature, should be so held by its possessors, that it cannot improve, but must die with each individual. Having no advantages of previous education, they cannot arrange their thoughts; they can hardly be said to think. They can far less express or communicate to others the intuitive knowledge which they possess; and their art, acquired by habit alone, is little different from an instinct. We are as little entitled to expect improvement here as in the architecture of the bee or the beaver. The species (pardon the the allusion, ye generous hearts of oak!) cannot improve. Yet a ship is a machine. We know the forces which act on it, and we know the results of its construction; all these are as fixed as the laws of motion. What hinders this to be reduced to a set of practical maxims, as well founded and as logically deduced as the working of a steam-engine or a cotton mill. The stoker or the spinner acts only with his hands, and may "whistle as he works, for want of thought;" but the mechanist, the engineer, thinks for him, improves his machine, and directs him to a better practice. May not the rough seaman look for the same assistance; and may not the ingenious speculist in his closet unravel the intricate thread of mechanism which connects all the manual operations with the unchangeable laws of nature, and both furnish the seaman with a better machine, and direct him to a more dexterous use of it.

which has been zealously cultivated by the French philosophers.

We cannot help thinking that much may be done; nay, we may say that much has been done. We think highly of the progressive labours of Renaud, Pitot, Bouguer, Du Hamel, Groignard, Bernoulli, Euler, Romme, and others; and are both surprised and sorry that Britain has contributed so little in these attempts. Gordon is the only one of our countrymen who has given a professedly scientific treatise on a small branch of the subject. The government of France has always been strongly impressed with the notion of great improvements being attainable by systematic study of this art; and we are indebted to the endeavours of that ingenious nation for any thing of practical importance that has been obtained. M. Bouguer was professor of hydrology at one of the marine academies of France, and was enjoined, as part of his duty, to compose dissertations both on the construction and the working of ships. His *Traité du Navire*, and his *Manœuvre des Vaisseaux*, are undoubtedly very valuable performances. So are those of Euler and Bernoulli, considered as mathematical dissertations, and they are wonderful works of genius, considered as the productions of persons who hardly ever saw a ship, and were totally unacquainted with the profession of a seaman. In this respect Bouguer had great superiority, having always lived at a sea-port, and having made many very long voyages. His treatises, therefore, are infinitely better accommodated to the demands of the seaman, and more directly instructive; but still the author is more a mathematician than an artist, and his performance is intelligible only to mathematicians. It is true, the academical education of the young gentlemen of the French navy is such, that a great number of them may acquire the preparatory knowledge that is necessary; and we are well informed that, in this respect, the officers of the British navy are greatly inferior to them.

Argument against the utility of their performances;

But this very circumstance has furnished to many persons an argument against the utility of those performances. It is said, that "notwithstanding this superior mathematical education, and the possession of those boasted performances of M. Bouguer, the French are greatly inferior, in point of seamanship, to our countrymen, who have not a page in their language to instruct them, and who could not peruse it if they had." Nay, so little do the French themselves seem sensible of the advantage of these publications, that no person among them has attempted to make a familiar abridgment of them, written in a way fitted to attract attention; and they still remain neglected in their original abstruse and uninteresting form.

We wish that we could give a satisfactory answer to this observation. It is just, and it is important. These very ingenious and learned dissertations are by no means so useful as we should expect. They are large books, and appear to contain much; and as their plan is logical, it seems to occupy the whole subject, and therefore to have done almost all that can be done. But, alas! they have only opened the subject, and the study is yet in its infancy. The whole science of the art must proceed on the knowledge of the impulsions of the wind and water. These are the forces which act on the machine; and its motions, which are the ultimatum of our research, whether as an end to be obtained or as a thing to be prevented, must depend on these forces. Now it is with respect to this fundamental point that we are as yet almost totally in the dark. And in the performances of M. Bouguer, as also in those of the other authors we have named, the theory of these forces, by which their quantity and the direction of their action are ascertained, is altogether erroneous; and its results deviate so enormously from what is observed in the motions of a ship, that the persons who should direct the operations on shipboard, in conformity to the maxims deducible from M. Bouguer's propositions, would be baffled in most of his attempts, and be in danger of losing the ship. The whole proceeds on the supposed truth of that theory which states the impulse of a fluid to be in the proportion of the square of the sine of the angle of incidence; and that its action on any small portion, such as a square foot of the sails or hull, is the same as if that portion were detached from the rest, and were exposed, single and alone, to the wind or water in the same angle. But we have shewn, in the article RESISTANCE OF FLUIDS, both from theory and experience, that both of these principles are erroneous, and this to a very great degree, in cases which occur most frequently in practice, that is, in the small angles of inclination. When the wind falls nearly perpendicular on the sails, theory is not very erroneous; but in these cases, the circumstances of the ship's situation are generally such that the practice is easy, occurring almost without thought; and in this case too, even considerable deviations from the very best practice are of no great moment. The interesting cases, where the intended movement requires or depends upon very oblique actions of the wind on the sails, and its practicability or impracticability depends on a very small variation of this obliquity; a mistake of the force, either as to intensity or direction, produces a mighty effect on the resulting motion. This is the case in sailing to windward, the most important of all the general problems of seamanship. The trim of the sails, and the course of the ship, so as to gain most on the wind, are very nice things; that is, they are confined within very narrow limits, and a small mistake produces a very considerable effect. The same thing obtains in many of the nice problems of tacking, box-hauling, wearing after lying-to in a storm, &c.

---

[1] The references in this article are all made to articles written by Professor Robison, and which are reprinted in the present edition.

which are confessedly erroneous in their fundamental principles;

The error in the second assertion of the theory is still greater, and the action on one part of the sail or hull is so greatly modified by its action on another adjoining part, that a stay-sail is often seen hanging like a loose rag, although there is nothing between it and the wind; and this merely because a great sail in its neighbourhood sends off a lateral stream of wind, which completely hinders the wind from getting at it. Till the theory of the action of fluids be established, therefore, we cannot tell what are the forces which are acting on every point of the sail and hull; therefore we cannot tell either the mean intensity or direction of the whole force which acts on any particular sail, nor the intensity and mean direction of the resistance to the hull; circumstances absolutely necessary for enabling us to say what will be their energy in producing a rotation round any particular axis. In like manner, we cannot, by such a computation, find the spontaneous axis of conversion, (see ROTATION), or the velocity of such conversion. In short, we cannot pronounce with tolerable confidence *a priori* what will be the motions in any case, or what dispositions of the sails will produce the movement we wish to perform. The experienced seaman learns by habit the general effects of every disposition of the sails; and though his knowledge is far from being accurate, it seldom leads him into any very blundering operation. Perhaps he seldom makes the best adjustment possible, but seldomer still does he deviate very far from it; and in the most general and important problems, such as working to windward, the result of much experience and many corrections has settled a trim of the sails, which is certainly not far from the truth, but, it must be acknowledged, deviates widely and uniformly from the theories of the mathematician's closet. The honest tar, therefore, must be indulged in his joke on the useless labours of the mathematician, who can neither hand, reef, nor steer.

After this account of the theoretical performances in the art of seamanship, and what we have said in another place on the small hopes we entertain of seeing a perfect theory of the impulse of fluids, it will not be expected that we enter very minutely on the subject in this place; nor is it our intention. But let it be observed that the theory is defective in one point only; and although this is a most important point, and the errors in it destroy the conclusions of the chief propositions, the reasonings remain in full force, and the *modus operandi* is precisely such as is stated in the theory. The *principles* of the art are therefore to be found in these treatises; but false inferences have been drawn, by computing from erroneous quantities. The rules and the practice of the computation, however, are still beyond controversy. Nay, since the process of investigation is legitimate, we may make use of it in order to discover the very circumstance in which we are at present mistaken; for by converting the proposition, instead of finding the motions by means of the supposed forces, combined with the known mechanism, we may discover the forces by means of this mechanism and the observed motions.

though use may be made of them.

Design of this article.

We shall therefore in this place give a very general view of the movements of a ship under sail, showing how they are produced and modified by the action of the wind on her sails, the water on her rudder and on her bows. We shall not attempt a precise determination of any of these movements; but we shall say enough to enable the curious landsman to understand how this mighty machine is managed amidst the fury of the winds and waves; and, what is more to our wish, we hope to enable the uninstructed but thinking seaman, to generalise that knowledge which he possesses; to class his ideas, and give them a sort of rational system; and even to improve his practice, by making him sensible of the immediate operation of every thing he does, and in what manner it contributes to produce the movement which he has in view.

A ship considered as in free space, impelled and resisted by opposite forces.

A ship may be considered at present as a mass of inert matter in free space, at liberty to move in every direction, according to the forces which impel or resist her; and when she is in actual motion, in the direction of her course, we may still consider her as at rest in absolute space, but exposed to the impulse of a current of water moving equally fast in the opposite direction; for in both cases the pressure of the water on her bows is the same; and we know that it is possible, and frequently happens in currents, that the impulse of the wind on her sails, and that of the water on her bows, balance each other so precisely, that she not only does not stir from the place, but also remains steadily in the same position, with her head directed to the same point of the compass. This state of things is easily conceived by any person accustomed to consider mechanical subjects, and every seaman of experience has observed it. It is of importance to consider it in this point of view, because it gives us the most familiar notion of the manner in which these forces of the wind and water are set in opposition, and made to balance or not to balance each other by the intervention of the ship, in the same manner as the goods and the weights balance each other in the scales by the intervention of a beam or steelyard.

Impulse of the wind on th sails opposite to that of the water on the bows.

When a ship proceeds steadily in her course, without changing her rate of sailing, or varying the direction of her head, we must in the first place conceive the accumulated impulses of the wind on all her sails as precisely equal and directly opposite to the impulse of the water on her bows. In the next place, because the ship does not change the direction of her keel, she resembles the balanced steelyard, in which the energies of the two weights, which tend to produce rotations in opposite directions, and thus to change the position of the beam, mutually balance each other round the fulcrum; so the energies of the actions of the wind on the different sails balance the energies of the water on the different parts of the hull.

Skill of the seaman displayed in shaping his course.

The seaman has two principal tasks to perform. The first is to keep the ship steadily in that course which will bring her farthest on in the line of her intended voyage. This is frequently very different from that line, and the choice of the best course is sometimes a matter of considerable difficulty. It is sometimes possible to shape the course precisely along the line of the voyage; and yet the intelligent seaman knows that he will arrive sooner, or with greater safety, at his port, by taking a different course; because he will gain more by increasing his speed than he loses by increasing the distance. Some principle must direct him in the selection of this course. This we must attempt to lay before the reader.

Having chosen such a course as he thinks most advantageous, he must set such a quantity of sail as the strength of the wind will allow him to carry with safety and effect, and must trim the sails properly, or so adjust their positions to the direction of the wind, that they may have the greatest possible tendency to impel the ship in the line of her course, and to keep her steadily in that direction.

His other task is to produce any deviations which he sees proper from the present course of the ship; and to produce these in the most certain, the safest, and the most expeditious manner. It is chiefly in this movement that the mechanical nature of a ship comes into view, and it is here that the superior address and resources of an expert seaman is to be perceived.

Under the article Sailing, some notice has been taken of the first task of the seaman, and it was there shown how a ship, after having taken up her anchor and fitted her sails, accelerates her motion, by degrees which continually diminish, till the increasing resistance of the water becomes precisely equal to the diminished impulse of the wind, and then the motion continues uniformly the same, so long as the wind continues to blow with the same force, and in the same direction.

It is perfectly consonant to experience, that the impulse of fluids is in the duplicate ratio of the relative velocity. Let it be supposed that when water moves one foot per second, its perpendicular pressure or impulse on a square foot is m pounds. Then, if it be moving with the velocity V estimated in feet per second, its perpendicular impulse on a surface S, containing any number of square feet, must be $m\,SV^2$.

In like manner, the impulse of air on the same surface may be represented by $n\,SV^2$; and the proportion of the impulse of these two fluids will be that of m to n. We may express this by the ratio of q to 1, making $\frac{m}{n}=q$.

Impulse of the water computed in ounces on the square foot.

M. Bouguer's computations and tables are on the supposition that the impulse of sea-water moving one foot per second is twenty-three ounces on a square foot, and that the impulse of the wind is the same when it blows at the rate of twenty-four feet per second. These measures are all French. They by no means agree with the experiments of others; and what we have already said, when treating of the Resistance of Fluids, is enough to show us that nothing like precise measures can be expected. It was shown, as the result of a rational investigation, and confirmed by the experiments of Buat and others, that the impulsions and resistances at the same surface, with the same obliquity of incidence, and the same velocity of motion, are different according to the form and situation of the adjoining parts. Thus the total resistance of a thin board is greater than that of a long prism, having this board for its front or bow, &c.

We are greatly at a loss what to give as absolute measures of these impulsions.

1. With respect to water. The experiments of the French academy on a prism two feet broad and deep, and four feet long, indicate a resistance of 0·973 pounds avoirdupois to a square foot, moving with the velocity of one foot per second at the surface of still water.

Mr. Buat's experiments on a square foot wholly immersed in a stream, were as follow:

A square foot as a thin plate................	1·81	pounds
Ditto as the front of a box one foot long..	1·42	...
Ditto as the front of a box three feet long.	1·29	...

The resistance of sea water is about $\frac{1}{23}$ greater.

2. With respect to air the varieties are as great. The resistance of a square foot to air moving with the velocity of one foot per second, appears from Mr. Robins's experiments on sixteen square inches to be, on a square

foot...	0·001596	pounds.
Chevalier Borda's on sixteen inches	0·001757	...
.... on eighty-one inches	0·002042	...
Mr. Rouse's on large surfaces.........	0·002291	...

Precise measures are not to be expected, nor are they necessary in this inquiry. Here we are chiefly interested in their proportions, as they may be varied by their mode of action in the different circumstances of obliquity and velocity.

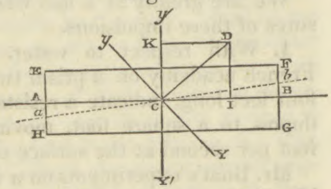
Direct impulse on the sail perpendicular to the yard.

We begin by recurring to the fundamental proposition concerning the impulse of fluids, viz. that the absolute pressure is always in a direction perpendicular to the impelled surface, whatever may be the direction of the stream of fluid. We must therefore illustrate the doctrine, by always supposing a flat surface of sail stretched on a yard, which can be braced about in any direction, and giving this sail such a position and such an extent of surface, that the impulse on it may be the same, both as to direction and intensity, with that on the real sails. Thus the consideration is greatly simplified. The direction of the impulse is therefore perpendicular to the yard. Its intensity depends on the velocity with which the wind meets the sail, and the obliquity of its stroke. We shall adopt the constructions founded on the common doctrine, that the impulse is as the square of the sine of the inclination, because they are simple; whereas, if we were to introduce the values of the oblique impulses, such as they have been observed in the excellent experiments of the Academy of Paris, the constructions would be complicated in the extreme, and we could hardly draw any consequences which would be intelligible to any but expert mathematicians. The conclusions will be erroneous, not in kind but in quantity only; and we shall point out the necessary corrections, so that the final results will be found not very different from real observation.

A ship compared to an oblong box.

If a ship were a round cylindrical body like a flat tub, floating on its bottom, and fitted with a mast and sail in the centre, she would always sail in a direction perpendicular to the yard. This is evident. But she is an oblong body, and may be compared to a chest, whose length greatly exceeds its breadth. She is so shaped, that a moderate force will push her through the water with the head or stern foremost; but it requires a very great force to push her sideways with the same velocity. A fine sailing ship or war will require about twelve times as much force to push her sideways as to push her head foremost. In this respect, therefore, she will very much resemble a chest whose length is twelve times its breadth; and whatever be the proportion of these resistances in different ships, we may always substitute a box which shall have the same resistances headways and sideways.

Fig. 1.



Makes lee way when not sailing directly before the wind.

Let EFGH (fig. 1.) be the horizontal section of such a box, and AB its middle line, and C its centre. In whatever direction this box may chance to move, the direction of the whole resistance on its two sides will pass through C. For as the whole stream has one inclination to the side EF, the equivalent of the equal impulses on every part will be in a line perpendicular to the middle of EF. For the same reason, it will be in a line perpendicular to the middle of FG. These perpendiculars must cross in C. Suppose a mast erected at C, and YC*y* to be a yard hoisted on it carrying a sail. Let the yard be first conceived as braced right athwart at right angles to the keel, as represented by Y′*y*′. Then, whatever be the direction of the wind abaft this sail, it will impel the vessel in the direction CB. But if the sail has the oblique position Y*y*, the impulse will be in the direction CD perpendicular to CY, and will both push the vessel ahead and sideways: For the impulse CD is equivalent to the two impulses CK and CI (the sides of a rectangle of which CD is the diagonal). The force CI pushes the vessel ahead, and CK pushes her sideways. She must therefore take some intermediate direction *ab*, such that the resistance of the water to the plane FG is to its resistance to the plane EF as CI to CK.

The angle *b*CB between the real course and the direction of the head is called the leeway; and in the course of this dissertation we shall express it by the symbol *x*. It evidently depends on the shape of the vessel and on the position of the yard. An accurate knowledge of the quantity of leeway, corresponding to different circumstances of obliquity of impulse, extent of surface, &c. is of the utmost importance in the practice of navigation; and even an approximation is valuable. The subject is so very difficult that this must content us for the present.

Let V be the velocity of the ship in the direction C*b*, and let the surfaces FG and FE be called A′ and B′. Then the resistance to the lateral motion is $m\mathrm{V}^2\times\mathrm{B}'\times\text{sine}^2, b\mathrm{CB}$, and that to the direct motion is $m\mathrm{V}^2\times\mathrm{A}'\times\text{sine}^2, b\mathrm{CK}$, or $m\mathrm{V}^2\times\mathrm{A}'\times\cos^2 b\mathrm{CB}$. Therefore these resistances are in the proportion of $\mathrm{B}'\times\text{sine}^2, x$ to $\mathrm{A}'\times\cos.^2, x$ (representing the angle of leeway *b*CB by the symbol *x*).

Therefore we have CI : CK, or $\mathrm{CI}:\mathrm{ID}=\mathrm{A}'\cdot\cos.^2 x:\mathrm{B}'\cdot\text{sine}^2 x, =\mathrm{A}':\mathrm{B}'\cdot\dfrac{\text{sine}^2 x}{\cos.^2 x}=\mathrm{A}':\mathrm{B}'\cdot\text{tangent}^2 x$.

How to find the quantity of leeway

Let the angle YCB, to which the yard is braced up, be called the trim of the sails, and expressed by the symbol *b*. This is the complement of the angle DCI. Now $\mathrm{CI}:\mathrm{ID}=\text{rad.}:\tan.\ \mathrm{DCI}, =1:\tan.\ \mathrm{DCI}, =1:\text{cotan.}\ b$. Therefore we have finally $1:\text{cotan.}\ b=\mathrm{A}':\mathrm{B}'\cdot\tan.^2 x$, and $\mathrm{A}'\cdot\text{cotan.}\ b=\mathrm{B}'\cdot\text{tangent}^2 x$, and $\tan.^2 x=\dfrac{\mathrm{A}'}{\mathrm{B}'}\cot.\ b$. This equation evidently ascertains the mutual relation between the trim of the sails and the leeway, in every case where we can tell the proportion between the resistances to the direct and broadside motions of the ship, and where this proportion does not change by the obliquity of the course. Thus, suppose the yard braced up to an angle of 30° with the keel. Then $\text{cotan.}\ 30°=1{\cdot}732$ very nearly. Suppose also that the resistance sideways is twelve times greater than the resistance headways. This gives $\mathrm{A}=1$ and $\mathrm{B}'=12$. Therefore $1{\cdot}732=12\times\text{tangent}^2 x$, and $\text{tangent}^2 x=\dfrac{1{\cdot}732}{12}, =0{\cdot}14434$, and $\tan.\ x=0{\cdot}3799$, and $x=20°\ 48'$, very nearly two points of leeway.

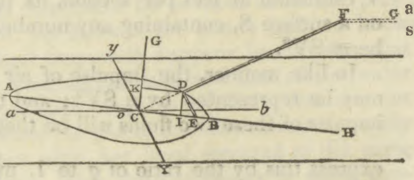
This computation, or rather the equation which gives room for it, supposes the resistances proportional to the squares of the sines of incidence. The experiments of the Academy of Paris, of which an abstract is given in the article Resistance of Fluids, show that this supposition is not far from the truth when the angle of incidence is great. In the present case the angle of incidence on the front FG is about 70°, and the experiments just now mentioned, show that the real resistances exceed the theoretical ones only $\frac{1}{180}$. But the angle of incidence on EF is only 20° 48′. Experiment shows that in this inclination the resistance is almost quadruple of the theoretical resistances. Therefore the lateral resistance is assumed much too small in the present instance. Therefore a much smaller leeway will suffice for producing a lateral resistance which will balance the lateral impulse CK, arising from the obliquity of the sail, viz. 30°. The matter of fact is, that a pretty good sailing ship, with her sails braced to this angle at a medium, will not make above five or six degrees leeway in smooth water and easy weather; and yet in this situation the hull and rigging present a very great surface to the wind, in the most improper positions, so as to have a very great effect in increasing her leeway. And if we compute the resistances for this leeway of six degrees by the actual experiments of the French Academy on the angle, we shall find the result not far from the truth; that is, the direct and lateral resistances will be nearly in the proportion of CI to ID.

which depends on trim of the sails.

It results from this view of the matter, that the leeway is in general much smaller than what the usual theory assigns. We also see, that according to whatever law the resistances change by a change of inclination, the leeway remains the same while the trim of the sails is the same. The leeway depends only on the direction of the impulse of the wind; and this depends solely on the position of the sails with respect to the keel, whatever may be the direction of the wind. This is a very important observation, and will be frequently referred to in the progress of the present investigation. Note, however, that we are here considering only the action on the sails, and on the same sails. We are not considering the action of the wind on the hull and rigging. This may be very considerable; and it is always in a lee direction, and augments the leeway; and its influence must be so much the more sensible, as it bears a greater proportion to the impulse on the sails. A ship under courses, or close-reefed topsails and courses, must make more leeway than when under all her canvass, trimmed to the same angle. But to introduce this additional cause of deviation here, would render the investigation too complicated to be of any use.

Illustration of this doctrine by experiments on models and on ships.

Fig. 2.

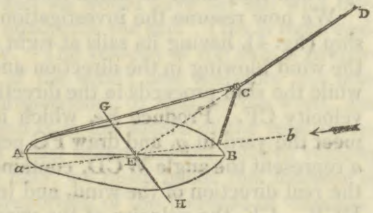


This doctrine will be considerably illustrated by attending to the manner in which a lighter is tracked along a canal, or swings to its anchor in a stream. The track-rope is made fast to some staple or bolt E on the deck (fig. 2), and is passed between two of the timber-heads of the bow D, and laid hold of at F on shore. The men or cattle walk along the path FG, the rope keeps extended in the direction DF, and the lighter arranges itself in an oblique position AB, and is thus dragged along in the direction *ab*, parallel to the side of the canal. Or, if the canal has a current in the opposite direction *ba*, the lighter may be kept steady in its place by the rope DF made fast to a post at F. In this case, it is always observed, that the lighter swings in a position AB, which is oblique to the stream *ab*. Now, the force which retains it in this position, and which precisely balances the action of the stream, is certainly exerted in the direction DF; and the lighter would be held in the same manner if the rope were made fast at C amidship, without any dependence on the timberheads at D; and it would be held in the same position, if, instead of the single rope CF, it were riding by two ropes CG and CH, of which CH is in a direction right ahead, but oblique to the stream, and the other CG is perpendicular to CH or AB. And, drawing DI and DK perpendicular to AB and CG, the strain on the rope CH is to that on the rope CG as CI to CK. The action of the rope in these cases is precisely analogous to that of the sail *y*Y; and the obliquity of the keel to the direction of the motion, or to the direction of the stream, is analogous to the leeway. All this must be evident to any person accustomed to mechanical disquisitions.

A most important use may be made of this illustration. If an accurate model be made of a ship, and if it be placed in a stream of water, and ridden in this manner by a rope made fast at any point D of the bow, it will arrange itself in some determined position AB. There will be a certain obliquity to the stream, measured by the angle B*ob;* and there will be a corresponding obliquity of the rope, measured by the angle FCB. Let *y*CY be perpendicular to CF. Then CY will be the position of the yard, or trim of the sails corresponding to the leeway *b*CB. Then, if we shift the rope to a point of the bow distant from D by a small quantity, we shall obtain a new position of the ship, both with respect to the stream and rope; and in this way may be obtained the relation between the position of the sails and the leeway, independent of all theory, and susceptible of great accuracy; and this may be done with a variety of models suited to the most usual forms of ships.

In further thinking on this subject, we are persuaded that these experiments, instead of being made on models, may with equal ease be made on a ship of any size. Let the ship ride in a stream at a mooring D (fig. 3), by means of a short hawser BCD from her bow, having a spring AC on it carried out from her quarter. She will swing to her moorings, till she ranges herself in a certain position AB with respect to the direction *ba* of the stream; and the direction of the hawser DC will point to some point E of the line of the keel. Now, it is plain to any person acquainted with mechanical disquisitions, that the deviation BE*b* is precisely the leeway that the ship will make when the average position of the sails is that of the line GEH perpendicular to ED; at least this will give the leeway which is produced by the sails alone. By heaving on the spring, the knot C may be brought into any other position we please; and for every new position of the knot the ship will take a new position with respect to the stream and to the hawser. And we persist in saying, that more information will be got by this train of experiments than from any mathematical theory: for all the theories of the impulses of fluids must proceed on physical postulates with respect to the motions of the filaments, which are exceedingly conjectural.

Fig. 3.



The comparison of a ship to an oblong body is only useful to give clear notions on the subject.

And it must now be farther observed, that the substitution which we have made of an oblong parallelopiped for a ship, although well suited to give us clear notions of the subject, is of small use in practice; for it is next to impossible (even granting the theory of oblique impulsions) to make this substitution. A ship is of a form which is not reducible to equations; and therefore the action of the water on her bow or broadside can only be had by a most laborious and intricate calculation for almost every square foot of its surface.[1] And this must be different for every ship. But, which is more unlucky, when we have got a parallelopiped which will have the same proportion of direct and lateral resistance for a particular angle of leeway, it will not answer for another leeway of the same ship; for when the leeway changes, the figure actually exposed to the action of the water changes also. When the leeway is increased, more of the lee-quarter is acted on by the water, and a part of the weather-bow is now removed from its action. Another parallelopiped must therefore be discovered, whose resistances shall suit this new position of the keel with respect to the real course of the ship.

We therefore beg leave to recommend this train of experiments to the notice of the Association for the Improvement of Naval Architecture, as a very promising method for ascertaining this important point.[2] And we proceed, in the next place, to ascertain the relation between the velocity of the ship and that of the wind, modified as they may be by the trim of the sails and the obliquity of the impulse.

The relation between the velocity of the ship and wind ascertained.

Let AB (figs. 4, 5, and 6), represent the horizontal section of a ship. In place of all the drawing sails, that is, the sails which are really filled, we can always substitute one sail of equal extent, trimmed to the same angle with the keel. This being supposed attached to the yard DCD, let this yard be first of all at right angles to the keel, as represented in fig. 4. Let the wind blow in the direction WC, and let CE (in the direction WC continued) represent the velocity V of the wind. Let CF be the velocity *v* of the ship. It must also be in the direction of the ship's motion, because when the sail is at right angles to the keel, the absolute impulse on the sail is in the direction of the keel, and there is no lateral impulse, and consequently no leeway. Draw EF, and complete the parallelogram CFE*e*, producing *e*C through the centre of the yard to *w*. Then *w*C will be the relative or apparent direction of the wind, and C*e* or FE will be its apparent or relative velocity. For if the line C*e* be carried along CF, keeping always parallel to its first position, and if a particle of air move uniformly along CE (a fixed line in absolute space) in the same time, this particle will always be found in that point of CE, where it is intersected at that instant by the moving line C*e;* so that if C*e* were a tube, the particle of air, which

[1] Bezout's *Cours de Mathem.* vol. v. p. 72, &c.

[2] This society was instituted on the 14th of April 1791, in consequence of the patriotic and energetic endeavours of Mr. J. Sewell, a bookseller of Cornhill, who was proprietor of the European Magazine, the covers of which periodical be had for a long time previous to this date, gratuitously devoted to the reception of communications for the improvement of naval architecture. The society consisted of about one hundred and fifty noblemen and gentlemen, and numbered among its members some of the most distinguished men in the kingdom. His late Majesty was the president. The Earls Stanhope, Leicester, and Uxbridge, Lords Radnor and Mulgrave, Sir John Borlase Warren, Sir Joseph Banks, and Sir Charles Middleton, were vice-presidents. Unfortunately its energies were expended in the futile examination of plans, to the neglect of the more sure course for the improvement of an infant science—the investigation of principles. The consequence was, that dissatisfied at the absence of all useful results from their labours, the members gradually ceased to take an interest in them, and the society fell to pieces, without, we believe, any formal dissolution. Had the members adopted the suggestions of Professor Robison, and their energies and resources been directed by his talents and experience, how different might have been the result!

really moves in the line CE, would always be found in the tube Ce. While CE is the real direction of the wind, Ce will be the position of the vane at the mast head, which will therefore mark the apparent direction of the wind, or its motion relative to the moving ship.

We may conceive this in another way. Suppose a cannon-shot fired in the direction CE at the passing ship, and that it passes through the mast at C with the velocity of the wind. It will not pass through the off-side of the ship at P, in the line CE; for while the shot moves from C to P, the point P has gone forward, and the point p is now in the place where P was when the shot passed through the mast. The shot will therefore pass through the ship's side in the point p, and a person on board seeing it pass through C and p will say that its motion was in the line Cp.

When a ship is in motion the apparent direction of the wind is always different from the real direction.

Thus it happens, that when a ship is in motion the apparent direction of the wind is always ahead of its real direction. The line wC is always found within the angle WCB. It is easy to see from the construction, that the difference between the real and apparent directions of the wind is so much the more remarkable as the velocity of the ship is greater. For the angle WCw or ECe depends on the magnitude of Ee or CF, in proportion to CE. Persons not much accustomed to attend to these matters are apt to think all attention to this difference to be nothing but affectation of nicety. They have no notion that the velocity of a ship can have any sensible proportion to that of the wind. "Swift as the wind," is a proverbial expression; yet the velocity of a ship always bears a very sensible proportion to that of the wind, and even very frequently exceeds it. We may form a pretty exact notion of the velocity of the wind by observing the shadows of the summer clouds flying along the face of a country, and it may be very well measured by this method. The motion of such clouds cannot be very different from that of the air below; and when the pressure of the wind on a flat surface, while blowing with a velocity measured in this way, is compared with its pressure when its velocity is measured by more unexceptionable methods, they are found to agree with all desirable accuracy. Now observations of this kind frequently repeated, show that what we call a pleasant brisk gale blows at the rate of about ten miles an hour, or about fifteen feet in a second, and exerts a pressure of half a pound on a square foot. Mr. Smeaton has frequently observed the sails of a windmill, driven by such a wind, moving faster, nay much faster, towards their extremities, so that the sail, instead of being pressed to the frames on the arms, was taken aback, and fluttering on them. Nay, we know that a good ship, with all her sails set, and the wind on the beam, will in such a situation sail above ten knots an hour in smooth water. There is an observation made by every experienced seaman, which shows this difference between the real and apparent directions of the wind very distinctly. When a ship that is sailing briskly with the wind on the beam tacks about, and then sails equally well on the other tack, the wind always appears to have shifted and come more ahead. This is familiar to all seamen. The seaman judges of the direction of the wind by the position of the ship's vanes. Suppose the ship sailing due west on the starboard tack, with the wind apparently N.N.W., the vane pointing S.S.E. If the ship put about, and stands due east on the larboard tack, the vane will be found no longer to point S.S.E., but perhaps S.S.W., the wind appearing N.N.E., and the ship must be nearly close-hauled in order to make an east course. The wind appears to have shifted four points. If the ship tacks again, the wind returns to its old quarter. We have often observed a greater difference than this. The celebrated astronomer Dr. Bradley, taking the amusement of sailing in a pinnace on the river Thames, observed this, and was surprised at it, imagining that the change of the wind was owing to the approaching to or retiring from the shore. The boatmen told him that it always happened at sea, and explained it to him in the best manner they were able. The explanation struck him, and set him a musing on an astronomical phenomenon which he had been puzzled by for some years, and which he called the aberration of the fixed stars. Every star changes its place a small matter for half a year, and returns to it at the completion of the year. He compared the stream of light from the star to the wind, and the telescope of the astronomer to the ship's vane, while the earth was like the ship, moving in opposite directions when in the opposite point of its orbit. The telescope must always be pointed ahead of the real direction of the star, in the same manner as the vane is always in a direction ahead of the wind; and thus he ascertained the progressive motion of light, and discovered the proportion of its velocity to the velocity of the earth in its orbit, by observing the deviation which was necessarily given to the telescope. Observing that the light shifted its direction about 40″, he concluded its velocity to be about 11,000 times greater than that of the earth; just as the intelligent seaman would conclude from this apparent shifting of the wind, that the velocity of the wind is about triple that of the ship. This is indeed the best method for discovering the velocity of the wind. Let the direction of the vane at the mast-head be very accurately noticed on both tacks, and let the velocity of the ship be also accurately measured. The angle between the directions of the ship's head on these different tacks being halved, will give the real direction of the wind, which must be compared with the position of the vane in order to determine the angle contained between the real and apparent directions of the wind or the angle ECe; or half of the observed shifting of the wind will show the inclination of its true and apparent directions. This being found, the proportion of EC to FC (fig. 6), is easily measured.

Observation of Dr. Bradley on this subject.

We have been very particular on this point, because since the mutual actions of bodies depend on their relative motions only, we should make prodigious mistakes if we estimated the action of the wind by its real direction and velocity, when they differ so much from the relative or apparent.

Velocity of a ship when its sails are at right angles to the keel.

We now resume the investigation of the velocity of the ship (fig. 4), having its sails at right angles to the keel, and the wind blowing in the direction and with the velocity CE, while the ship proceeds in the direction of the keel with the velocity CF. Produce Ee, which is parallel to BC, till it meet the yard in g, and draw FG perpendicular to Eg. Let a represent the angle WCD, contained between the sail and the real direction of the wind, and let b be the angle of trim DCB. CE, the velocity of the wind, was expressed by V, and CF, the velocity of the ship, by v.

The absolute impulse on the sail is (by the usual theory) proportional to the square of the relative velocity, and to the square of the sine of the angle of incidence; that is, to $\text{FE}^2 \times \sin.^2 w\text{CD}$. Now the angle $\text{GFE} = w\text{CD}$, and EG is equal to $\text{FE} \times \sin.\,\text{GFE}$; and EG is equal to $\text{E}g - g\text{G}$. But $\text{E}g = \text{EC} \times \sin.\,\text{EC}g, = \text{V} \times \sin.\,a$; and $g\text{G} = \text{CF}, = v$. Therefore $\text{EG} = \text{V} \times \sin.\,a - v$, and the impulse is proportional to $(\text{V} \times \sin.\,a - v)^2$. If S represent the surface of the sail, the impulse, in pounds, will be $n\text{S}(\text{V} \times \sin.\,a - v)^2$.

Let A be the surface which, when it meets the water perpendicularly with the velocity v, will sustain the same pressure or resistance which the bows of the ship actually meet with. This impulse, in pounds, will be $m\text{A}v^2$. Therefore, because we are considering the ship's motion as in a state of uniformity, the two pressures balance each other; and therefore $m\text{A}v^2 = n\text{S}(\text{V} \times \sin.\,a - v)^2$ and $\frac{m}{n}\text{A}v^2 = \text{S}(\text{V} \times \sin.\,a - v)^2$;

therefore $\sqrt{\frac{m}{n}}\sqrt{\text{A}} \times v = \sqrt{\text{S}} \times \text{V} \times \sin.\,a - v\sqrt{\text{S}}$, and $v =$

$$\frac{\sqrt{\text{S}} \times \text{V} \times \sin.\,a}{\sqrt{\frac{m}{n}\text{A}} + \sqrt{\text{S}}} = \frac{\text{V} \times \sin.\,a}{\sqrt{\frac{m\text{A}}{n\text{S}}} + 1} = \frac{\text{V} \times \sin.\,a}{\sqrt{q\frac{\text{A}}{\text{S}}} + 1}.$$

We see, in the first place, that the velocity of the ship is, *cæteris paribus*, proportional to the velocity of the wind, and to the sine of its incidence on the sail jointly; for while the surface of the sail S and the equivalent surface for the bow remains the same, v increases or diminishes at the same rate with $V \cdot \sin. a$. When the wind is right astern, the sine of a is unity, and then the ship's velocity is $\dfrac{V}{\sqrt{\dfrac{mA}{nS}}+1}$.

Note, that the denominator of this fraction is a common number; for m and n are numbers and A and S being quantities of one kind, $\dfrac{A}{S}$ is also a number.

It must also be carefully attended to, that S expresses a quantity of sail actually receiving wind with the inclination a. It will not always be true, therefore, that the velocity will increase as the wind is more abaft, because some sails will then becalm others. This observation is not, however, of great importance; for it is very unusual to put a ship in the situation considered hitherto; that is, with the yards square, unless she be right before the wind.

If we should discover the relation between the velocity and the quantity of sail in this simple case of the wind right aft, observe that the equation $v = \dfrac{V}{\sqrt{\dfrac{mA}{nS}}+1}$, gives us $\sqrt{\dfrac{mA}{nS}}\,v + v = V$, and $\sqrt{\dfrac{mA}{nS}}\,v = V - v$, and $\dfrac{mA}{nS}\,v^2 = \overline{V-v}^2$, and $\dfrac{nS}{mA} = \dfrac{v^2}{(V-v)^2}$; and because n and m and A are constant quantities, S is proportional to $\dfrac{v^2}{(V-v)^2}$, or the surface of sail is proportional to the square of the ship's velocity directly, and to the square of the relative velocity inversely. Thus, if a ship be sailing with one-eighth of the velocity of the wind, and we would have her sail with one-fourth of it, we must quadruple the sail. This is more easily seen in another way. The velocity of the ship is proportional to the velocity of the wind; and therefore the relative velocity is also proportional to that of the wind, and the impulse of the wind is as the square of the relative velocity. Therefore, in order to increase the relative velocity by an increase of sail only, we must make this increase of sail in the duplicate proportion of the increase of velocity.

Let us, in the next place, consider the motion of a ship whose sails stand oblique to the keel.

Its velocity when the sails stand oblique to the keel.

The construction for this purpose differs a little from the former, because, when the sails are trimmed to any oblique position DCB, (figs. 5 and 6), there must be a deviation from the direction of the keel, or a leeway B*Cb*. Call this x. Let CF be the velocity of the ship. Draw, as before, Eg perpendicular to the yard, and FG perpendicular to Eg; also, draw FH perpendicular to the yard: then, as before, EG, which is in the subduplicate ratio of the impulse on the sail, is equal to Eg—Gg. Now Eg is, as before, $= V \times \sin. a$, and Gg is equal to FH, which is $= CF \times \sin. FCH$, or $= v \times \sin. (b+x)$. Therefore we have the impulse $= nS(V \cdot \sin. a - v \cdot \sin. (b+x))^2$.

This expression of the impulse is perfectly similar to that in the former case, its only difference consisting in the subductive part, which is here $v \times \sin. \overline{b+x}$ instead of v. But it expresses the same thing as before, viz. the diminution of the impulse. The impulse being reckoned solely in the direction perpendicular to the sail, it is diminished solely by the sail withdrawing itself *in that direction* from the wind; and as gE may be considered as the real impulsive motion of the wind, GE must be considered as the relative and effective impulsive motion. The impulse would have been the same had the ship been at rest, and had the wind met it perpendicularly with the velocity GE.

Fig. 5.

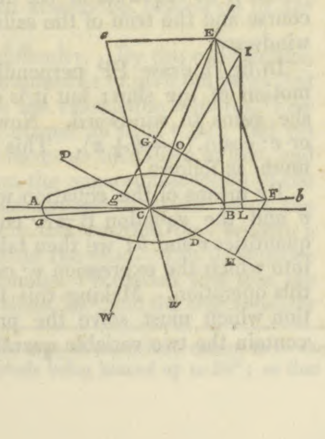

Fig. 6.

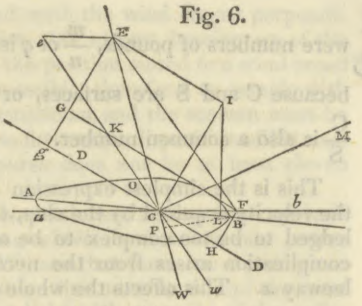


We must now show the connexion between this impulse and the motion of the ship. The sail, and consequently the ship, is pressed by the wind in the direction CI perpendicular to the sail or yard with the force which we have just now determined. This (in the state of uniform motion) must be equal and opposite to the action of the water. Draw IL at right angles to the keel. The impulse in the direction CI (which we may measure by CI) is equivalent to the impulses CL and LI. By the first the ship is impelled right forward, and by the second she is driven sideways. Therefore we must have a leeway, and a lateral as well as a direct resistance. We suppose the form of the ship to be known, and therefore the proportion is known, or discoverable, between the direct and lateral resistances corresponding to every angle x of leeway. Let A be the surface whose perpendicular resistance is equal to the direct resistance of the ship corresponding to the leeway x, that is, whose resistance is equal to the resistance really felt by the ship's bows in the direction of the keel when she is sailing with this leeway; and let B in like manner be the surface whose perpendicular resistance is equal to the actual resistance to the ship's motion in the direction LI, perpendicular to the keel. (This is not equivalent to A′ and B′ adapted to the rectangular box, but to $A' \cdot \cos.^2 x$ and $B' \cdot \sin.^2 x$). We have therefore $A : B = CL : LI$, and $LI = \dfrac{CL \cdot B}{A}$. Also, because $CI = \sqrt{CL^2 + LI^2}$, we have $A : \sqrt{A^2+B^2} = CL : CI$, and $CI = \dfrac{CL \cdot \sqrt{A^2+B^2}}{A}$. The resistance in the direction LC is properly measured by $m\,A\,v^2$ as has been already observed. Therefore the resistance in the direction IC must be expressed by $m\sqrt{A^2+B^2}|v^2$; or (making C the surface which is equal to $\sqrt{A^2+B^2}$, and which will therefore have the same perpendicular resistance to the water having the velocity v) it may be expressed by mCv^2.

Connection between the impulse and motion of the ship.

Therefore, because there is an equilibrium between the impulse and resistance, we have $mCv^2 = nS(V \cdot \sin. a - v \cdot \sin. \overline{b+x})^2$, and $\dfrac{m}{n}\,Cv^2$, or $qCv^2 = S(V \cdot \sin. a - v \cdot \sin. \overline{b+x})^2$, and $\sqrt{q}\sqrt{C}v = \sqrt{S}(V \cdot \sin. a - v \cdot \sin. \overline{b+x})$.

$$\text{Therefore } v = \frac{\sqrt{S} \cdot V \cdot \sin. a}{\sqrt{q}\sqrt{C} + \sqrt{S} \cdot \sin. \overline{b+x}}, = \frac{V \cdot \sin. a}{\sqrt{q}\dfrac{\sqrt{C}}{\sqrt{S}} + \sin. \overline{b+x}} = V\frac{\text{Sin. } a}{\sqrt{q}\dfrac{\sqrt{C}}{\sqrt{S}} + \sin. \overline{b+x}}.$$

Observe that the quantity which is the coefficient of V in this equation is a common number; for sin. a is a number, being a decimal fraction of the radius 1, sin. $\overline{b+x}$ is also a number, for the same reason. And since m and n

were numbers of pounds, $\frac{m}{n}$ or q is a common number. And because C and S are surfaces, or quantities of one kind, $\frac{C}{S}$ is also a common number.

This is the simplest expression that we can think of for the velocity acquired by the ship, though it must be acknowledged to be too complex to be of very prompt use. Its complication arises from the necessity of introducing the leeway x. This affects the whole of the denominator; for the surface C depends on it, because C is $=\sqrt{A^2+B^2}$, and A and B are analogous to $A'\cos.^2x$ and $B'\sin{}^2x$.

Important consequences deduced from the foregoing theorem.

But we can deduce some important consequences from this theorem.

While the surface S of the sail actually filled by the wind remains the same, and the angle DCB, which in future we shall call the trim of the sails, also remains the same, both the leeway x and the substituted surface C remains the same. The denominator is therefore constant; and the velocity of the ship is proportional to $\sqrt{S}\cdot V\cdot\sin.a$; that is, directly as the velocity of the wind, directly as the absolute inclination of the wind to the yard, and directly as the square root of the surface of the sails.

We also learn from the construction of the figure, that FG parallel to the yard cuts CE in a given ratio. For CF is in a constant ratio to Eg, as has been just now demonstrated. And the angle DCF is constant. Therefore CF $\cdot$ sin. b, or FH or Gg, is proportional to Eg, and OC to EC, or EC is cut in one proportion, whatever may be the angle ECD, so long as the angle DCF is constant.

We also see that it is very possible for the velocity of the ship on an oblique course to exceed that of the wind. This will be the case when the number $\frac{\sin.a}{\sqrt{q\frac{C}{S}}+\sin.\overline{b+x}}$ exceeds unity, or when sin. a is greater than $\sqrt{q\frac{C}{S}}+\sin.\overline{b+x}$.

Now this may easily be by sufficiently enlarging S and diminishing $b+x$. It is indeed frequently seen in fine sailers with all their sails set and not hauled too near the wind.

We remarked above, that the angle of leeway x affects the whole denominator of the fraction which expresses the velocity. Let it be observed that the angle ICL is the complement of LCD, or of b. Therefore, CL : LI, or A:B=1: tan. ICL=1 : cot. b, and B=A $\cdot$ cotan. b. Now A is equivalent to $A'\cdot\cos.^2x$, and thus b becomes a function of x. C is evidently so, being $\sqrt{A^2+B^2}$. Therefore before the value of this fraction can be obtained, we must be able to compute, by our knowledge of the form of the ship, the value of A for every angle x of leeway. This can be done only by resolving her bows into a great number of elementary planes, and computing the impulses on each and adding them into one sum. The computation is of immense labour, as may be seen by one example given by Bouguer. When the leeway is but small, not exceeding ten degrees, the substitution of the rectangular prism of one determined form is abundantly exact for all leeways contained within this limit; and we shall soon see reason for being contented with this approximation. We may now make use of the formula expressing the velocity for solving the chief problems in this part of the seaman's task.

Problem I: To determine the best position of the sails for standing on a given course, when the direction and velocity of the wind and its angle with the course are given.

And first let it be required to determine the best position of the sail for standing on a given course ab, when CE the direction and velocity of the wind, and its angle with the course WCF, are given. This problem has exercised the talents of the mathematicians ever since the days of Newton. In the article PNEUMATICS we gave the solution of one very nearly related to it, namely, to determine the position of the sail which would produce the greatest impulse in the direction of the course. The solution was to place the yard CD in such a position that the tangent of the angle FCD may be one half of the tangent of the angle DCW. This will indeed be the best position of the sail for beginning the motion; but as soon as the ship begins to move in the direction CF, the effective impulse of the wind is diminished, and also its inclination to the sail. The angle DCw diminishes continually as the ship accelerates; for CF is now accompanied by its equal eE, and by an angle ECe, or WCw. CF increases, and the impulse on the sail diminishes, till an equilibrium obtains between the resistance of the water and the impulse of the wind. The impulse is now measured by $CE^2\times\sin.{}^2e$CD instead of $CE^2\times\sin.{}^2$ECD, that is, by EG^2 instead of Eg^2.

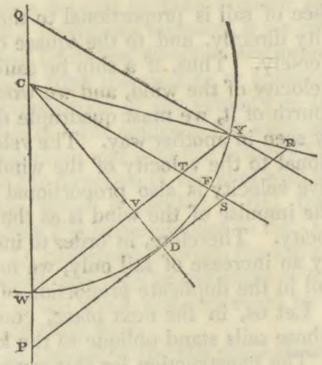
This introduction of the relative motion of the wind renders the actual solution of the problem extremely difficult. It is very easily expressed geometrically: Divide the angle wCF in such a manner that the tangent of DCF may be half of the tangent of DCw, and the problem may be constructed geometrically as follows.

Let WCF (fig. 7.) be the angle between the sail and course. Round the centre C describe the circle WDFY; produce WC to Q, so that CQ$=\frac{1}{3}$WC, and draw QY parallel to CF cutting the circle in Y; bisect the arch WY in D, and draw DC. DC is the proper position of the yard.

Draw the cord WY, cutting CD in V and CF in T; draw the tangent PD, cutting CF in S and CY in R.

It is evident that WY, PR, are both perpendicular to CD, and arc bisected in V and D; therefore (by reason of the parallels QY, CF) 4 : 3=QW : CW,=YW : TW, RP : SP. Therefore PD : PS=2 : 3, and PD:DS=2:1. Q.E.D. But this division cannot be made to the best advantage till the ship has attained its greatest velocity, and the angle w CF has been produced.

Fig. 7



We must consider all the three angles, a, b, and x, as variable in the equation which expresses the value of v, and we must make the fluxion of this equation=0; then, by means of the equation B=A$\cdot$ contan. b, we must obtain the value of b and of $\dot{b}$ in terms of x and $\dot{x}$. With respect to a, observe, that if we make the angle WCF$=p$, we have $p=a+b+x$; and p being a constant quantity, we have $\dot{a}+\dot{b}+\dot{x}=0$. Substituting for a, b, $\dot{a}$, and $\dot{b}$, their values in terms of x and $\dot{x}$, in the fluxionary equation=0, we readily obtain x, and then a and b, which solves the problem.

Let it be required, in the next place, to determine the course and the trim of the sails most proper for plying to windward.

Prob. II. To determine the course and trim of the sails most proper for plying to windward.

In fig. 6, draw FP perpendicular to WC. CF is the motion of the ship; but it is only by the motion PC that she gains to windward. Now CP is=CF$\times$cosin. WCF, or $v\cdot$ cosin. $(a+b+x)$. This must be rendered a maximum, as follows.

By means of the equation which expresses the value of v and the equation B=A$\cdot$ cotan. b, we exterminate the quantities v and b; we then take the fluxion of the quantity into which the expression $v\cdot$ cos. $(a+b+x)$ is changed by this operation. Making this fluxion=0, we get the equation which must solve the problem. This equation will contain the two variable quantities a and x with their fluxions; then make the coefficient of $\dot{x}$ equal to 0, also the coefficient of $\dot{a}$ equal to 0. This will give two equations, which will determine a and x, and from this we get $b=p-a-x$.

Prob. III. To determine the best course and trim of the sails for getting away from a given line of coast.

Should it be required, in the third place, to find the best course and trim of the sails for getting away from a given line of coast CM (fig. 6.), the process perfectly resembles this last, which is in fact getting away from a line of coast which makes a right angle with the wind. Therefore, in place of the angle WCF, we must substitute the angle WCM±WCF. Call this angle e. We must make $v\cdot\cos.(e\pm a\pm b\pm x)$ a maximum. The analytical process is the same as the former, only e is here a constant quantity.

Observations on the preceding problems.

These are the three principal problems which can be solved by means of the knowledge that we have obtained of the motion of the ship when impelled by an oblique sail, and therefore making leeway; and they may be considered as an abstract of this part of M. Bouguer's work. We have only pointed out the process for this solution, and have even omitted some things taken notice of by M. Bezout in his very elegant compendium. Our reasons will appear as we go on. The learned reader will readily see the extreme difficulty of the subject, and the immense calculations which are necessary even in the simplest cases, and will grant that it is out of the power of any but an expert analyst to derive any use from them; but the mathematician can calculate tables for the use of the practical seaman Thus he can calculate the best position of the sails for advancing in a course 90° from the wind, and the velocity in that course; then for 85°, 80°, 75°, &c. M. Bouguer has given a table of this kind; but to avoid the immense difficulty of the process, he has adapted it to the apparent direction of the wind. We have inserted a few of his numbers, suited to such cases as can be of service, namely, when all the sails draw, or none stand in the way of others. Column 1st is the apparent angle of the wind and course; column 2d is the corresponding angle of the sails and keel; and column 3d is the apparent angle of the sails and wind.

M. Bouguer's table for finding the best position of the sails for advancing in any course.

1 *w* CF	2 DCB	3 *w*CD
103°53′	42°30′	61°23′
99 13	40 —	59 13
94 25	37 30	56 55
89 28	35 —	54 28
84 23	32 30	51 53
79 06	30 —	49 06
73 39	27 30	46 09
68 —	25 —	43 —

In all these numbers we have the tangent of *w*CD double of the tangent of DCF.

Inutility of these calculations.

But this is really doing but little for the seaman. The apparent direction of the wind is unknown to him till the ship is sailing with uniform velocity; and he is still uninformed as to the leeway. It is, however, of service to him to know, for instance, that when the angle of the vanes and yards is 56 degrees, the yard should be braced up to 37° 30′, &c.

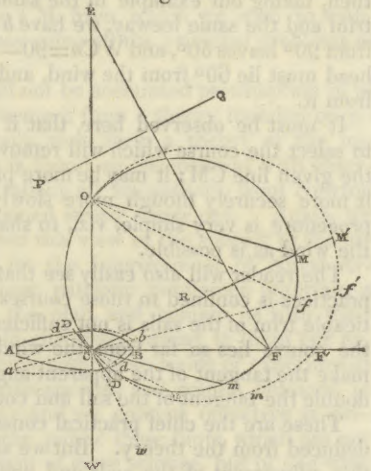
But here occurs a new difficulty. By the construction of a square-rigged ship it is impossible to give the yards that inclination to the keel which the calculation requires.[1] Few ships can have their yards braced up to 37° 30′; and yet this is required in order to have an incidence of 56°, and to hold a course 94° 25′ from the apparent direction of the wind, that is, with the wind apparently 4° 25′ abaft the beam. A good sailing ship in this position may acquire a velocity even exceeding that of the wind. Let us suppose it only one half of this velocity. We shall find that the angle WC*w* is in this case about 29°, and the ship is nearly going 123° from the wind, with the wind almost perpendicular to the sail; therefore this utmost bracing up of the sails is only giving them the position suited to a wind broad on the quarter. It is impossible, therefore, to comply with the demand of the mathematician, and the seaman must be contented to employ a less favourable disposition of his sails in all cases where his course does not lie at least eleven points from the wind.

Let us see whether this restriction, arising from necessity, leaves any thing in our choice, and makes one course preferable to another. We see that there are a prodigious number of courses, and these the most usual and the most important, which we must hold with one trim of the sails; in particular, sailing with the wind on the beam, and all cases of plying to windward, must be performed with this unfavourable trim of the sails. We are certain that the smaller we make the angle of incidence, real or apparent, the smaller will be the velocity of the ship; but it may happen that we shall gain more to windward, or get sooner away from a lee-coast, or any object of danger, by sailing slowly on one course than by sailing quickly on another.

We have seen that while the trim of the sails remains the same, the leeway and the angle of the yard and course remains the same, and that the velocity of the ship is as the sine of the angle of real incidence, that is, as the sine of the angle of the sail and the real direction of the wind.

Let the ship AB (fig. 8.) hold the course CF, with the wind blowing in the direction WC, and having her yards DCD braced up to the smallest angle BCD which the rigging can admit. Let CF be to CE as the velocity of the ship to the velocity of the wind; join FE and draw C*w* parallel to EF; it is evident that FE is the relative motion of the wind, and *w*CD is the relative incidence on the sail.

Fig. 8.



Draw FO parallel to the yard DC, and describe a circle through the points COF; then we say that if the ship, with the same wind and the same trim of the same drawing sails, be made to sail on any other course C*f*, her velocity along CF is to the velocity along C*f* as CF is to C*f*; or, in other words, the ship will employ the same time in going from C to any point of the circumference CFO.

Join *f*O. Then, because the angles CFO, C*f*O are on the same cord CO, they are equal, and *f*O is parallel to *d*C*d*, the new position of the yard corresponding to the new position of the keel *ab*, making the angle *d*C*b*=DCB. Also, by the nature of the circle, the line CF is to C*f* as the sine of the angle CFO to the sine of the angle CO*f*, that is (on account of the parallels CD, OF and C*d*, O*f*), as the sine of WCD to the sine of WC*d*. But when the trim of the sails remains the same, the velocity of the ship is as the sine of the angle of the sail with the direction of the wind; therefore CF is to C*f* as the velocity on CF to that on C*f*, and the proposition is demonstrated.

To determine the best course for avoiding a rock.

Let it now be required to determine the best course for avoiding a rock R lying in the direction CR, or for withdrawing as fast as possible from a line of coast PQ. Draw CM through R, or parallel to PQ, and let m be the middle of the arch C*m*M. It is plain that m is the most remote from CM of any point of the arch C*m*M, and therefore the ship will recede farther from the coast PQ in any given time, by holding the course C*m* than by any other course.

---

[1] There are few of the modern men-of-war which cannot have their yards braced up to 27°, instead of 37° 30′. We may assume that most ships will admit of their yards being braced up to 30°; so that the angle of incidence would be 49° 06′, and the course 79° 06′.

This course is easily determined; for the arch C*m*M =360°—(arch CO+arch OM), and the arch CO is the measure of twice the angle CFO, or twice the angle DCB, or twice $\overline{b+x}$, and the arch OM measures twice the angle ECM.

Thus, suppose the sharpest possible trim of the sails to be 35°, and the observed angle ECM to be 70°; then CO+OM is 70°+140° or 210°. This being taken from 360°, leaves 150°, of which the half M*m* is 75°, and the angle MC*m* is 37° 30′. This added to ECM makes EC*m* 170° 30′, leaving WC*m*=72° 30′, and the ship must hold a course making an angle of 72° 30′ with the real direction of the wind, and WCD will be 37° 30′.

This supposes no leeway. But if we know that under all the sail which the ship can carry with safety and advantage she makes 5 degrees of leeway, the angle DC*m* of the sail and course, or $b+x$, is 40°. Then CO+OM=220°, which being taken from 360°, leaves 140°, of which the half is 70°, =M*m*, and the angle MC*m*=35°, and EC*m*=105°, and WC*m*=75°, and the ship must lie with her head 70° from the wind, making 5 degrees of leeway, and the angle WCD is 35°.

The general rule for the position of the ship is, *that the line on shipboard which bisects the angle* b+x *may also bisect the angle* WCM, or make the angle between the course and the line, from which we wish to withdraw, equal to the angle between the sail and the real direction of the wind.

Corollaries.

It is plain that this problem includes that of plying to windward. We have only to suppose ECM to be 90°; then, taking our example in the same ship, with the same trim and the same leeway, we have $b+x=40°$. This taken from 90° leaves 50°, and WC*n*=90—25=65, and the ship's head must lie 60° from the wind, and the yard must be 25° from it.

It must be observed here, that it is not always eligible to select the course which will remove the ship fastest from the given line CM; it may be more prudent to remove from it more securely though more slowly. In such cases the procedure is very simple, viz., to shape the course as near the wind as is possible.

The reader will also easily see that the propriety of these practices is confined to those courses only where the practicable trim of the sails is not sufficiently sharp. Whenever the course lies so far from the wind that it is possible to make the tangent of the apparent angle of the wind and sail double the tangent of the sail and course, it should be done.

The adjustment of the sails supposed in the theory impracticable.

These are the chief practical consequences which can be deduced from the theory. But we should consider how far this adjustment of the sails and course can be performed. And here occur difficulties so great as to make it almost impracticable. We have always supposed the position of the surface of the sail to be distinctly observable and measurable; but this can be hardly affirmed even with respect to a sail stretched on a yard. Here we supposed the surface of the sail to have the same inclination to the keel that the yard has. This is by no means the case; the sail assumes a concave form, of which it is almost impossible to assign the direction of the mean impulse. We believe that this is always considerably to leeward of a perpendicular to the yard, lying between CI and CE, (fig. 6). This is of some advantage, being equivalent to a sharper trim. We cannot affirm this, however, with any confidence, because it renders the impulse on the weather-leech of the sail so exceedingly feeble as hardly to have any effect. In sailing close to the wind, the ship is kept so near that the weather-leech of the sail is almost ready to receive the wind edgewise, and to flutter or shiver. The most effective or drawing sails with a side-wind, especially when plying to windward, are the staysails. We believe that it is impossible to say, with anything approaching to precision, what is the position of the general surface of a staysail, or to calculate the intensity and direction of the general impulse; and we affirm with confidence that no man can pronounce on these points with any exactness. If we can guess within a third or a fourth part of the truth, it is all we can pretend to; and after all, it is but a guess. Add to this, the sails coming in the way of each other, and either becalming them or sending the wind upon them in a direction widely different from that of its free motion. All these points we think beyond our power of calculation, and therefore that it is in vain to give the seaman mathematical rules, or even tables of adjustment ready calculated; since he can neither produce that medium position of his sails that is required, nor tell what is the position which he employs.

This is one of the principal reasons why so little advantage has been derived from the very ingenious and promising disquisitions of Bouguer and other mathematicians, and has made us omit the actual solution of the chief problems, contenting ourselves with pointing out the process to such readers as have a relish for these analytical operations.

The theory itself erroneous,

But there is another principal reason for the small progress which has been made in the theory of seamanship. This is the error of the theory itself, which supposes the impulsions of a fluid to be in the duplicate ratio of the sine of incidence. The most careful comparison which has been made between the results of this theory and matter of fact, is to be seen in the experiments made by the members of the Royal Academy of Sciences at Paris, mentioned in the article Resistance of Fluids. We subjoin another abstract of them in the following table; where column 1st gives the angle of incidence; column 2d gives the impulsions really observed; column 3d the impulses, had they followed the duplicate ratio of the sines; and column 4th the impulses, if they were in the simple ratio of the sines.

Angle of incid.	Impulsion observed.	Impulse as sine.^{2}	Impulse as sine.
90	1000	1000	1000
84	989	989	995
78	958	957	978
72	908	905	951
66	845	835	914
60	771	750	866
54	693	655	809
48	615	552	743
42	543	448	669
36	480	346	587
30	440	250	500
24	424	165	407
18	414	96	309
12	406	43	208
6	400	11	105

Here we see an enormous difference in the great obliquities. When the angle of incidence is only six degrees, the observed impulse is forty times greater than the theoretical impulse; at 12° it is ten times greater; at 18° it is more than four times greater; and at 24° it is almost three times greater

and the deductions from it useless.

No wonder then that the deductions from this theory are so useless and so unlike what we familiarly observe. We took notice of this when we were considering the leeway of a rectangular box, and thus saw a reason for admitting an incomparably smaller leeway than what would result from the laborious computations necessary by the theory. This error in theory has as great an influence on the impulsions of air when acting obliquely on a sail; and the experiments of Mr. Robins and of the Chevalier Borda, on the oblique impulsions of air, are perfectly conformable (as far as they go) to those of the academicians on water. The oblique impulsions of the wind are therefore much more efficacious for pressing the ship in the direction of her course than the theory allows us to suppose; and the progress of a ship plying to windward is much greater, both because the oblique impulses of the wind are more effective, and because the leeway is much smaller, than we suppose. Were not this the case, it would be impossible for a square-rigged ship to get to windward. The impulse on her sails, when close hauled, would be so trifling, that she would not have a third part of the velocity which we see her acquire: and this trifling velocity would be wasted in leeway; for we have seen that the diminution of the oblique impulses of the water is accompanied by an increase of leeway. But we see that in the great obliquities the impulsions continue to be very considerable, and that even an incidence of six degrees gives an impulse as great as the theory allows to an incidence of 40°. We may therefore, on all occasions, keep the yards more square; and the loss which we sustain by the diminution of the very oblique impulse will be more than compensated by its more favourable direction with respect to the ship's keel. Let us take an example of this. Suppose the wind about two points before the beam, making an angle of 68° with the keel. The theory assigns 43° for the inclination of the wind to the sail, and 15° for the trim of the sail. The perpendicular impulse being supposed 1000, the theoretical impulse for 45° is 465. This reduced in the proportion of radius to the sine of 25°, gives the impulse in the direction of the course only 197.

But if we ease off the lee-braces till the yard makes an angle of 50° with the keel, and allows the wind an incidence of no more than 18°, we have the experimented impulse 414, which, when reduced in the proportion of radius to the sine of 50°, gives an effective impulse 317. In like manner, the trim 56°, with the incidence 12°, gives an effective impulse 337; and the trim of 62°, with the incidence only 6°, gives 353.

Hence it would at first sight appear that the angle DCB of 62° and WCD of 6° would be better for holding a course within six points of the wind than any more oblique position of the sails; but it will only give a greater initial impulse. As the ship accelerates, the wind apparently comes ahead, and we must continue to brace up as a ship freshens her way. It is not unusual for her to acquire half or two-thirds of the velocity of the wind; in which case the wind comes apparently ahead more than two points, when the yards must be braced up to 35°, and thus allows an impulse no greater than about 7°. Now, this is very frequently observed in good ships, which, in a brisk gale and smooth water, will go five or six knots close-hauled, the ship's head six points from the wind, and the sails no more than just full, but ready to shiver by the smallest luff. All this would be impossible by the usual theory; and in this respect these experiments of the French Academy give a fine illustration of the seaman's practice. They account for what we should otherwise be much puzzled to explain; and the great progress which is made by a ship close-hauled being perfectly agreeable to what we should expect from the law of oblique impulsions, deducible from these so often-mentioned experiments, while it is totally incompatible with the common theory, should make us abandon the theory without hesitation, and strenuously set about the establishment of another, founded entirely on experiments. For this purpose the experiments should be made on the oblique impulsions of air, on as great a scale as possible, and in as great a variety of circumstances, so as to furnish a series of impulsions for all angles of obliquity. We have but four or five experiments on this subject, viz., two by Mr. Robins, and two or three by the Chevalier Borda. Having thus gotten a series of impulsions, it is very practicable to raise on this foundation a practical institute, and to give a table of the velocities of a ship suited to every angle of inclination and of trim; for nothing is more certain than the resolution of the impulse perpendicular to the sail into a force in the direction of the keel, and a lateral force.

Experiments proper for establishing another.

We are also disposed to think that experiments might be made on a model very nicely rigged with sails, and trimmed in every different degree, which would point out the mean direction of the impulse on the sails, and the comparative force of these impulses on different directions of the wind. The method would be very similar to that for examining the impulse of the water on the hull. If this can also be ascertained experimentally, the intelligent reader will easily see that the whole motion of a ship under sail may be determined for every case. Tables may then be constructed by calculation, or by graphical operations, which will give the velocities of a ship in every different course, and corresponding to every trim of sail. And let it be here observed, that the trim of the sail is not to be estimated in degrees of inclination of the yards; because, as we have already remarked, we cannot observe nor adjust the lateen sails in this way. But, in making the experiments for ascertaining the impulse, the exact position of the tacks and sheets of the sails are to be noted; and this combination of adjustments is to pass by the name of a certain trim. Thus that trim of all the sails may be called 40, whose direction is experimentally found equivalent to a flat surface trimmed to the obliquity 40°.

Having done this, we may construct a figure for each trim similar to fig. 8, where, instead of a circle, we shall have a curve COM′F′, whose chords CF′, *c f′*, &c. are proportional to the velocities in these courses; and by means of this curve we can find the point *m′*, which is most remote from any line CM from which we wish to withdraw: and thus we may solve all the principal problems of the art.

We hope that it will not be accounted presumption in us to expect more improvement from a theory founded on judicious experiments only, than from a theory of the impulse of fluids, which is found so inconsistent with observation, and of whose fallacy all its authors, from Newton to D'Alembert, entertained strong suspicions. Again, we beg leave to recommend this view of the subject to the attention of the Society for the Improvement of Naval Architecture. Should these patriotic gentlemen entertain a favourable opinion of the plan, and honour us with their correspondence, we will cheerfully impart to them our notions of the way in which both these trains of experiments may be prosecuted with success, and results obtained in which we may confide; and we content ourselves at present with offering to the public these hints, which are not the speculations of a man of mere science, but of one who, with a competent knowledge of the laws of mechanical nature, has the experience of several years service in the royal navy, where the art of working ships was a favourite object of his scientific attention.

Recommended to the Society for the Improvement of Naval Architecture.

With those observations we conclude our discussion of the first part of the seaman's task, and now proceed to consider the means that are employed to prevent or to produce any deviations from the uniform rectilineal course which has been selected.

Means employed to prevent or produce deviations from a course.

Here the ship is be considered as a body in free space, convertible round her centre of inertia. For whatever may be the point round which she turns, this motion may always be considered as compounded of a rotation round an axis passing through her centre of gravity or inertia. She is impelled by the wind and by the water acting on many surfaces differently inclined to each other, and the impulse on each is perpendicular to the surface. In order therefore that she may continue steadily in one course, it is not only necessary that the impelling forces, estimated in their mean direction, be equal and opposite to the resisting forces estimated in their mean direction; but also that these two directions may pass through one point, otherwise she will be affected as a log of wood is when pushed in opposite directions by two forces, which are equal indeed, but are applied to different parts of the log. A ship must be considered as a lever, acted on in different parts by forces in different directions, and the whole balancing each other round that point or axis where the equivalent of all the resisting forces passes. This may be considered as a point supported by this resisting force and as a sort of fulcrum: therefore, in order that the ship may maintain her position, the energies or *momenta* of all the impelling forces round this point must balance each other.

Impulses on a ship sailing right before the wind different from those on her when sailing obliquely.

When a ship sails right afore the wind, with her yards square, it is evident that the impulses on each side of the keel are equal, as also their mechanical *momenta* round any axis passing perpendicularly through the keel. So are the actions of the water on her bows. But when she sails on an oblique course, with her yards braced on either side, she sustains a pressure in the direction CI (fig. 5,) perpendicular to the sail. This, by giving her a lateral pressure LI, as well as a pressure CL ahead, causes her to make leeway, and to move in a line C*b* inclined to CB. By this means the balance of action on the two bows is destroyed; the general impulse on the lee-bow is increased; and that on the weather-bow is diminished. The combined impulse is therefore no longer in the direction BC, but (in the state of uniform motion) in the direction IC.

Suppose that in an instant the whole sails are annihilated and the impelling pressure CI, which precisely balanced the resisting pressure on her bows, removed. The ship tends, by her inertia, to proceed in the direction C*b*. This tendency produces a continuation of the resistance in the opposite direction IC, which is not directly opposed to the tendency of the ship in the direction C*b*; therefore the ship's head would immediately come up to the wind. The experienced seaman will recollect something like this when the sails are suddenly lowered when coming to anchor. It does not happen solely from the obliquity of the action on the bows: It would happen to the parallelopiped of fig. 2, which was sustaining a lateral impulsion $B\cdot\sin.^2x$, and a direct impulsion $A\cdot\cos.^2x$. These are continued for a moment after the annihilation of the sail: but being no longer opposed by a force in the direction CD, but by a force in the direction C*b*, the force $B\cdot\sin.^2x$ must prevail, and the body is not only retarded in its motion, but its head turns towards the wind. But this effect of the leeway is greatly increased by the curved form of the ship's bows. This occasions the centre of effort of all the impulsions of the water on the leeside of the ship to be very far forward, and this so much the more remarkably as she is sharper afore. It is in general not much abaft the foremast. Now the centre of the ship's tendency to continue her motion is the same with her centre of gravity, and this is generally but a little before the mainmast. She is therefore in the same condition nearly as if she were pushed at the mainmast in a direction parallel to C*b*, and at the foremast by a force parallel to IC. The evident consequence of this is a tendency to come up to the wind. This is independent of all situation of the sails, provided only that they have been trimmed obliquely.

Griping.

This tendency of the ship's head to windward is called griping in the seaman's language, and is greatest in ships which are sharp forward, as we have said already. This circumstance is easily understood. Whatever is the direction of the ship's motion, the absolute impulse on that part of the bow immediately contiguous to B is perpendicular to that very part of the surface. The more acute, therefore, that the angle of the bow is, the more will the impulse on that part be perpendicular to the keel, and the greater will be its energy to turn the head to windward.

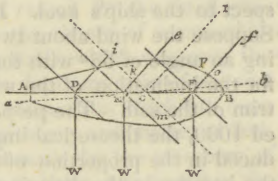
Propriety of the disposition of the sails of a ship.

Thus we are enabled to understand or to see the propriety of the disposition of the sails of a ship. We see her crowded with sails forward, and even many sails extended far before her bow, such as the spritsail, the bowsprit topsail, the fore-topmast staysail, the jib, and flying jib. The sails abaft are comparatively smaller. The sails on the mizenmast are much smaller than those on the foremast. All the staysails hoisted on the mainmast may be considered as headsails, because their centres of effort are considerably before the centre of gravity of the ship: and notwithstanding this disposition, it generally requires a small action of the rudder to counteract the windward tendency of the lee-bow. This is considered as a good quality when moderate; because it enables the seaman to throw the sails aback, and stop the ship's way in a moment, if she be in danger from any thing a-head; and the ship which does not carry a little of a weather helm, is always a dull sailer.

Action of the water and the sails.

In order to judge somewhat more accurately of the action of the water and sails, suppose the ship AB (fig. 9,) to have its sails on the mizenmast D, the mainmast E, and the foremast F, braced up or trimmed alike, and the three lines D *i*, E *e*, F *f*, perpendicular to the sails, are in the proportion of the impulses on the sails. The ship is driven a-head and to leeward, and moves in the path *a*C*b*. This path is so inclined to the line of the keel, that the medium direction of the resistance of the water is parallel to the direction of the impulse. A line CI may be drawn parallel to the lines D *i*, E *e*, F *f*, and equal to their sum: and it may be drawn from such a point C, that the actions on all the parts of the hull between C and B may balance the *momenta* of all the actions on the hull between C and A. This point may justly be called the *centre of effort*, or the *centre of resistance*. We cannot determine this point for want of a proper theory of the resistance of fluids. Nay, although experiments like those of the Parisian Academy should give us the most perfect knowledge of the intensity of the oblique impulses on a square foot, we should hardly be benefitted by them: for the action of the water on a square foot of the hull at *p*, for instance, is so modified by the intervention of the stream of water which has struck the hull about B, and glided along the bow B *op*, that the pressure on *p* is totally different from what it would have been were it a square foot or surface detached from the rest, and presented in the same position to the water moving in the direction *b*C. For it is found, that the resistances given to planes joined so as to form a wedge, or to curved surfaces, are widely different from the accumulated resistances, calculated for their separate parts, agreeably to the experiments of the academy on single surfaces. We therefore do not attempt to ascertain the point C by theory; but it may be accurately determined by the experiments which we have so strongly recommended; and we offer this as an additional inducement for prosecuting them.

Fig. 9.



Centre of effort.

To be determined by experiments.

Draw through C a line perpendicular to CI, that is, parallel to the sails; and let the lines of impulse of the three sails cut in the points *i*, *k*, and *m*. This line *im* may be considered as a lever, moveable round C, and acted on at the points *i*, *k*, and *m*, by three forces. The rotatory momentum of the sails on the mizenmast is $Di \times iC$; that of the sails on the mainmast is $Ee \times kC$; and the momentum of the sails on the foremast is $Ff \times mC$. The two first tend to press forward the arm C*i*, and then to turn the ship's head towards the wind. The action of the sails on the foremast tends to pull the arm C*m* forward, and produce a

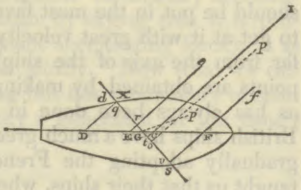
Equilibrium preserved by the position of the sails.

contrary rotation. If the ship under these three sails keeps steadily in her course, without the aid of the rudder, we must have $\mathrm{D}i \times i\mathrm{C} + \mathrm{E}e \times k\mathrm{C} = \mathrm{F}f \times m\mathrm{C}$. This is very possible, and is often seen in a ship under her mizen-topsail, main-topsail, and fore-topsail, all parallel to one another, and their surfaces duly proportioned by reefing. If more sails are set, we must always have a similar equilibrium. A certain number of them will have their efforts directed from the larboard arm of the lever im lying to leeward of CI, and a certain number will have their efforts directed from the starboard arm lying to windward of CI. The sum of the products of each of the first set, by their distances from C, must be equal to the sum of the similar products of the other set. As this equilibrium is all that is necessary for preserving the ship's position, and the cessation of it is immediately followed by a conversion; and as these states of the ship may be had by means of the three square sails only, when their surfaces are properly proportioned, it is plain that every movement may be executed and explained by their means. This will greatly simplify our future discussions. We shall therefore suppose in future that there are only the three topsails set, and that their surfaces are so adjusted by reefing, that their actions exactly balance each other round that point C of the middle line AB, where the actions of the water on the different parts of her bottom in like manner balance each other. This point C may be differently situated in the ship according to the leeway she makes, depending on the trim of the sails; and therefore although a certain proportion of the three surfaces may balance each other in one state of leeway, they may happen not to do so in another state. But the equilibrium is evidently attainable in every case, and we therefore shall always suppose it.

Consequence of destroying it.

It must now be observed, that when this equilibrium is destroyed, as, for example, by turning the edge of the mizen-topsail to the wind, which the seamen call *shivering* the mizen-topsail, and which may be considered as equivalent to the removing the mizen-topsail entirely, it does not follow that the ship will turn round the point C, this point remaining fixed. The ship must be considered as a free body, still acted on by a number of forces, which no longer balance each other; and she must therefore *begin* to turn round a spontaneous axis of conversion, which must be determined in the way set forth in the article ROTATION. It is of importance to point out in general where this axis is situated. Therefore let G (fig. 10.) be the centre of gravity of the ship. Draw the line qGv parallel to the yards, cutting $\mathrm{D}d$ in q, $\mathrm{E}e$ in r, CI in t, and $\mathrm{F}f$ in v. While the three sails are set, the line qv may be considered as a lever acted on by four forces, *viz.* $\mathrm{D}d$, impelling the lever forward perpendicularly in the point q; $\mathrm{E}e$, impelling it forward in the point r; $\mathrm{F}f$, impelling it forward in the point v; and CI, impelling it backward in the point t. These forces balance each other both in respect of progressive motion and of rotatory energy: for CI was taken equal to the sum of $\mathrm{D}d$, $\mathrm{E}e$, and $\mathrm{F}f$; so that no acceleration or retardation of the ship's progress in her course is supposed.

Fig. 10.



But by taking away the mizen-topsail, both the equilibriums are destroyed. A part $\mathrm{D}d$ of the accelerating force is taken away; and yet the ship, by her inertia or inherent force, tends, for a moment, to proceed in the direction $\mathrm{C}p$ with her former velocity; and by this tendency exerts for a moment the same pressure CI on the water, and sustains the same resistance IC. She must therefore be retarded in her motion by the excess of the resistance IC over the remaining impelling forces $\mathrm{E}e$ and $\mathrm{F}f$, that is, by a force equal and opposite to $\mathrm{D}d$. She will therefore be retarded in the same manner as if the mizen-topsail were still set, and a force equal and opposite to its action were applied to G, the centre of gravity, and she would soon acquire a smaller velocity, which would again bring all things into equilibrium; and she would stand on in the same course, without changing either her leeway or the position of her head.

But the equilibrium of the lever is also destroyed. It is now acted on by three forces only, viz. $\mathrm{E}e$ and $\mathrm{F}f$, impelling it forward in the points r and v, and IC impelling it backward in the point t. Make $rv : ro = \mathrm{E}e + \mathrm{F}f : \mathrm{F}f$, and make op parallel to CI and equal to $\mathrm{E}e + \mathrm{F}f$. Then we know, from the common principles of mechanics, that the force op acting at o will have the same momentum or energy to turn the lever round *any* point whatever as the two forces $\mathrm{E}e$ and $\mathrm{F}f$ applied at r and v; and now the lever is acted on by two forces, viz. IC, urging it backwards in the point t, and op urging it forwards in the point o. It must therefore turn round like a floating log, which gets two blows in opposite directions. If we now make $\mathrm{IC} - op : op = to : tx$, or $\mathrm{IC} - op : \mathrm{IC} = to : ox$, and apply to the point x a force equal to $\mathrm{IC} - op$ in the direction IC; we know by the common principles of mechanics, that this force $\mathrm{IC} - op$ will produce the same rotation round any point as the two forces IC and op applied in their proper directions at t and o. Let us examine the situation of the point x.

The force $\mathrm{IC} - op$ is evidently $= \mathrm{D}d$, and op is $= \mathrm{E}e + \mathrm{F}f$. Therefore $ot : tx = \mathrm{D}d : op$. But because, when all the sails were filled, there was an equilibrium round C, and therefore round t, and because the force op acting at o is equivalent to $\mathrm{E}e$ and $\mathrm{F}f$ acting at r and v, we must still have the equilibrium; and therefore we have the momentum $\mathrm{D}d \times qt = op \times ot$. Therefore $ot : tq = \mathrm{D}d : op$, and $tq = tx$. Therefore the point x is the same with the point q.

By shivering the mizen-top-sail.

Therefore, when we shiver the mizen-topsail, the rotation of the ship is the same as if the ship were at rest, and a force equal and opposite to the action of the mizen-topsail were applied at q or at D, or any point in the line $\mathrm{D}q$.

This might have been shown in another and shorter way. Suppose all sails filled, the ship is in equilibrio. This will be disturbed by applying to D a force opposite to $\mathrm{D}d$; and if the force be also equal to $\mathrm{D}d$, it is evident that these two forces destroy each other, and that this application of the force $d\mathrm{D}$ is equivalent to the taking away of the mizen-topsail. But we chose to give the whole mechanical investigation; because it gave us an opportunity of pointing out to the reader, in a case of very easy comprehension, the precise manner in which the ship is acted on by the different sails and by the water, and what share each of them has in the motion ultimately produced. We shall not repeat this manner of procedure in other cases, because a little reflection on the part of the reader will now enable him to trace the *modus operandi* through all its steps.

We now see that, in respect both of progressive motion and of conversion, the ship is affected by shivering the sail D, in the same manner as if a force equal and opposite to $\mathrm{D}d$ were applied at D, or at any point in the line $\mathrm{D}d$. We must now have recourse to the principles established under the article ROTATION.

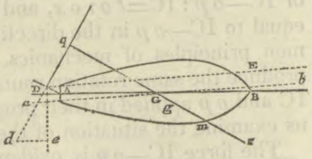
Let p represent a particle of matter, r its radius vector, or its distance $p\mathrm{G}$ from an axis passing through the centre of gravity G, and let M represent the whole quantity of matter of the ship. Then its momentum of inertia is $= \int p \cdot r^2$, (see ROTATION, No. 18.) The ship, impelled in the point D by a force in the direction $d\mathrm{D}$, will begin to turn round a spontaneous vertical axis, passing through a point S of the line $q\mathrm{G}$, which is drawn through the centre of gravity G, perpendicular to the direction $d\mathrm{D}$ of the external force, and the distance GS of this axis from the centre of gravity is $=\frac{\int p\cdot r^2}{M\cdot Gq}$ (see ROTATION, No. 96.), and it is taken on the opposite side of G from q, that is, S and q are on opposite sides of G.

Let us express the external force by the symbol F. It is equivalent to a certain number of pounds, being the pressure of the wind moving with the velocity V and inclination a on the surface of the sail D; and may therefore be computed either by the theoretical or experimental law of oblique impulses. Having obtained this, we can ascertain the angular velocity of the rotation and the absolute velocity of any given point of the ship by means of the theorems established in the article ROTATION.

Action of the rudder.

But before we proceed to this investigation, we shall consider the action of the rudder, which operates precisely in the same manner. Let the ship AB (fig. 11), have her rudder in the position AD, the helm being hard a-starboard, while the ship sailing on the starboard tack, and making leeway, keeps on the course *a b*. The lee surface of the rudder meets the water obliquely. The very foot of the rudder meets it in the direction DE parallel to *a b*. The parts farther up meet it with various obliquities, and with various velocities, as it glides round the bottom of the ship and falls into the wake. It is absolutely impossible to calculate the accumulated impulse. We shall not be far mistaken in the deflection of each contiguous filament, as it quits the bottom and glides along the rudder; but we neither know the velocity of these filaments, nor the deflection and velocity of the filaments gliding without them. We therefore imagine that all computations on this subject are in vain. But it is enough for our purpose that we know the direction of the absolute pressure which they exert on its surface. It is in the direction D*d*, perpendicular to that surface. We also may be confident that this pressure is very considerable, in proportion to the action of the water on the ship's bows, or of the wind on the sails; and we may suppose it to be nearly in the proportion of the square of the velocity of the ship in her course; but we cannot affirm it to be accurately in that proportion, for reasons that will readily occur to one who considers the way in which the water falls in behind the ship.

Fig. 11.



Greatest in a fine sailer.

It is observed, however, that a fine sailer always steers well, and that all movements by means of the rudder are performed with great rapidity when the velocity of the ship is great. We shall see by and by, that the speed with which the ship performs the angular movements is in the proportion of her progressive velocity: For we shall see that the squares of the times of performing the evolution are as the impulses inversely, which are as the squares of the velocities. There is perhaps no force which acts on a ship that can be more accurately determined by experiment than this. Let the ship ride in a stream or tideway whose velocity is accurately measured; and let her ride from two moorings, so that her bow may be a fixed point. Let a small tow line be laid out from her stern or quarter at right angles to the keel, and connected with some apparatus fitted up on shore or on board another ship, by which the strain on it may be accurately measured; a person conversant with mechanics will see many ways in which this can be done.

How to determine it.

Perhaps the following may be as good as any; let the end of the tow-line be fixed to some point as high out of the water as the point of the ship from which it is given out, and let this be very high. Let a block with a hook be on the rope, and a considerable weight hung on this hook. Things being thus prepared, put down the helm to a certain angle, so as to cause the ship to sheer off from the point to which the far end of the tow-line is attached. This will stretch the rope, and raise the weight out of the water. Now heave upon the rope, to bring the ship back again to her former position, with her keel in the direction of the stream. When this position is attained, note carefully the form of the rope, that is, the angle which its two parts make with the horizon. Call this angle a. Every person acquainted with these subjects knows that the horizontal strain is equal to half the weight multiplied by the cotangent of a, or that 2 is to the cotangent of a as the weight to the horizontal strain. Now it is this strain which balances and therefore measures the action of the rudder, or D*e* in fig. 11. Therefore, to have the absolute impulse D*d*, we must increase D*e* in the proportion of radius to the secant of the angle b, which the rudder makes with the keel. In a great ship sailing six miles in an hour, the impulse on the rudder inclined 30° to the keel is not less than 3000 pounds. The surface of the rudder of such a ship contains near 80 square feet. It is not, however, very necessary to know this absolute impulse D*d*, because it is its parts D*e* alone which measures the energy of the rudder in producing a conversion. Such experiments, made with various positions of the rudder, will give its energies corresponding to these positions, and will settle that long disputed point, which is the best position for turning a ship. On the hypothesis that the impulsions of fluids are in the duplicate ratio of the sines of incidence, there can be no doubt that it should make an angle of 54° 44′ with the keel. But the form of a large ship will not admit of this, because a tiller of a length sufficient for managing the rudder in sailing with great velocity has not room to deviate above 30° from the direction of the keel;[1] and in this position of the rudder the mean obliquity of the filaments of water to its surface cannot exceed 40° or 45°. A greater angle would not be of much service, for it is never for want of a proper obliquity that the rudder fails of producing a conversion.

Why a sh misses stays, &c

A ship misses stays in rough weather for want of a sufficient progressive velocity, and because her bows are beat off by the waves; and there is seldom any difficulty in wearing the ship, if she has any progressive motion. It is, however, always desirable to give the rudder as much influence as possible. Its surface should be enlarged (especially below) as much as can be done consistently with its strength, and with the power of the steersman to manage it; and it should be put in the most favourable situation for the water to get at it with great velocity; and it should be placed as far from the axis of the ship's motion as possible. These points are obtained by making the stern-post very upright, as has always been done in the French dockyards. The British ships have a much greater rake; but our builders are gradually adopting the French forms, experience having taught us that their ships, when in our possession, are much more obedient to the helm than our own.—In order to ascertain the motion produced by the action of the rudder, draw from the centre of gravity a line Gq perpendicular to D*d*, (D*d* being drawn through the centre of effort of the rudder). Then, as in the consideration of the action of the sails, we may conceive the line qG as a lever connected with the ship, and impelled by a force D*d* acting perpendicularly at q. The consequence of this will be, an incipient conversion of the ship about a vertical axis passing through some point S in the line qG, lying on the other side of G from q; and we have, as in the former case, $GS=\frac{\int p\cdot r^2}{M\cdot Gq}$.

The acti of the ru der simil to that o the sails, and very great.

Thus the action and effects of the sails and of the rudder are perfectly similar, and are to be considered in the same manner. We see that the action of the rudder, though of a small surface in comparison of the sails, must be very great: For the impulse of water is many hundred times greater than that of the wind; and the arm qG of the lever, by which it acts, is incomparably greater than that by which any of the impulsions on the sails produces its effect; accordingly the ship yields much more rapidly to its action than she does to the lateral impulse of a sail.

---

[1] In modern ships the improvements in the tillers will admit of the rudder's being put over so as to make an angle of 54° 44′ with the keel—the angle of maximum advantage assigned to it by theory.

Observe here, that if G were a fixed or supported axis, it would be the same thing whether the absolute force D*d* of the rudder acts in the direction D*d*, or its transverse parts D*e* acts in the direction D*e*, both would produce the same rotation; but it is not so in a free body. The force D*d* both tends to retard the ship's motion and to produce a rotation: It retards it as much as if the same force D*d* had been immediately applied to the centre. And thus the real motion of the ship is compounded of a motion of the centre in a direction parallel to D*d*, and of a motion round the centre. These two constitute the motion round S.

Employed as an example of the motions of conversion.

As the effects of the action of the rudder are both more remarkable and somewhat more simple than those of the sails, we shall employ them as an example of the mechanism of the motions of conversion in general; and as we must content ourselves, in a work like this, with what is very general, we shall simplify the investigation by attending only to the motion of conversion. We can get an accurate notion of the whole motion, if wanted for any purpose, by combining the progressive or retrograde motion parallel to D*d* with the motion of rotation which we are about to determine.

In this case, then, we observe, in the first place, that the angular velocity (see ROTATION, No. 22.) is $\frac{Dh \cdot qG}{\int pr^2}$; and, as was shewn in that article, this velocity of rotation increases in the proportion of the time of the forces' uniform action, and the rotation would be uniformly accelerated if the forces did really act uniformly. This, however, cannot be the case, because, by the ship's change of position and change of progressive velocity, the direction and intensity of the impelling force is continually changing. But if two ships are performing similar evolutions, it is obvious that the changes of force are similar in similar parts of the evolution. Therefore the consideration of the momentary evolution is sufficient for enabling us to compare the motions of ships actuated by similar forces, which is all we have in view at present. The velocity v, generated in any time t by the continuance of an invariable momentary acceleration, (which is all that we mean by saying that it is produced by the action of a constant accelerating force), is as the acceleration and the time jointly. Now what we call the *angular velocity* is nothing but this momentary acceleration. Therefore the velocity v generated in the time t is $= \frac{F \cdot qG}{\int pr^2} t$.

Angular velocity.

The expression of the angular velocity is also the expression of the velocity v of a point situated at the distance 1 from the axis G.

Let z be the space or arch of revolution described in the time t by this point, whose distance from G is $=1$. Then $\dot{z} = v\dot{t} = \frac{F \cdot qG}{\int pr^2} t\,\dot{t}$, and taking the fluent $z = \frac{F \cdot qG}{\int pr^2} t^2$. This arch measures the whole angle of rotation accomplished in the time t. These are therefore as the squares of the times from the beginning of the rotation.

Those evolutions are equal which are measured by equal arches. Thus two motions of 45 degrees each are equal. Therefore because z is the same in both, the quantity $\frac{F \cdot qG}{\int pr^2} t^2$ is a constant quantity, and t^2 is reciprocally proportional to $\frac{F \cdot qG}{\int pr^2}$, or is proportional to $\frac{\int pr^2}{F \cdot qG}$, and t is proportional to $\frac{\sqrt{\int pr^2}}{\sqrt{F \cdot qG}}$. That is to say, the times of the similar evolutions of two ships are as the square root of the momentum of inertia directly, and as the square root of the momentum of the rudder or sail inversely. This will enable us to make the comparison easily. Let us suppose the ships perfectly similar in form and rigging, and to differ only in length L and l; $\int P \cdot R^2$ is to $\int pr^2$ as L^5 to l^5. For the similar particles P and p contain quantities of matter which are as the cubes of their lineal dimensions, that is, as L^3 to l^3. And because the particles are similarly situated, R^2 is to r^2 as L^2 to l^2. Therefore $P \cdot R^2 : p \cdot r^2 = L^5 : l^5$. Now F is to f as L^2 to l^2. For the surfaces of the similar rudders or sails are as the squares of their lineal dimensions, that is, as L^2 to l^2. And, lastly, Gq is to gq as L to l, and therefore $F \cdot Gq : f \cdot gq = L^3 : l^3$. Therefore we have $T^2 : t^2 = \frac{\int P \cdot R^2}{F \cdot Gq} : \frac{\int p \cdot r^2}{f \cdot gq} = \frac{L^5}{L^3} : \frac{l^5}{l^3} = L^2 : l^2$, and $T : t = L : l$.

Times of similar evolutions with similar ships.

Therefore the times of performing similar evolutions with similar ships are proportional to the lengths of the ships when both are sailing equally fast; and since the evolutions are similar, and the forces vary similarly in their different parts, what is here demonstrated of the smallest incipient evolutions is true of the whole. They therefore not only describe equal angles of revolution, but also similar curves.

A small ship, therefore, works in less time and in less room than a great ship, and this in the proportion of its length. This is a great advantage in all cases, particularly in wearing, in order to sail on the other tack close-hauled. In this case she will always be to windward and a-head of the large ship, when both are got on the other tack. It would appear at first sight that the large ship will have the advantage in tacking. Indeed the large ship is farther to windward when again trimmed on the other tack than the small ship when she is just trimmed on the other tack. But this happened before the large ship had completed her evolution, and the small ship, in the mean time, has been going forward on the other tack, and going to windward. She will therefore be before the large ship's beam, and perhaps as far to windward.

We have seen that the velocity of rotation is proportional, *cæteris paribus*, to $F \times Gq$. F means the absolute impulse on the rudder or sail, and is always perpendicular to its surface. This absolute impulse on a sail depends on the obliquity of the wind to its surface. The usual theory says, that it is as the square of the sine of incidence; but we find this not true. We must content ourselves with expressing it by some as yet unknown function φ of the angle of incidence a, and call it φa; and if S be the surface of the sail, and V the velocity of the wind, the absolute impulse is $nV^2S \times \varphi a$. This acts (in the case of the mizen-topsail, fig. 10.) by the lever qG, which is equal to $DG \times \cos. DGq$, and DGq is equal to the angle of the yard and keel; which angle we formerly called b. Therefore its energy in producing a rotation is $nV^2S \times \varphi a \times DG \times \cos. b$. Leaving out the constant quantities n, V^2, S, and DG, its energy is proportional to $\varphi a \times \cos. b$. In order, therefore, that any sail may have the greatest power to produce a rotation round G, it must be so trimmed that $\varphi a \times \cos. b$ may be a maximum. Thus, if we would trim the sails on the foremast, so as to pay the ship off from the wind right a-head with the greatest effect, and if we take the experiments of the French academicians as proper measures of the oblique impulses of the wind on the sail, we will brace up the yard to an angle of 48 degrees with the keel. The impulse corresponding to 48 is 615, and the cosine of 48° is 669. These give a product of 411 435. If we brace the sail to 54·44, the angle assigned by the theory, the effective impulse is 405 274. If we make the angle 45°, the impulse is 408 774. It appears then that 48° is preferable to either of the others. But the difference is inconsiderable, as in all cases of maximum a small deviation from the best position is not very detrimental. But the difference between the theory and this experimental measure will be very great when the impulses of the wind are of necessity very oblique. Thus, in tacking ship, as soon as the headsails are taken aback, they serve to aid the evolution, as is evident: But if we were now to adopt the maxim inculcated by the theory, we should immediately round in the weather-braces, so as to increase the impulse on the sail, because it is then very small; and although we by this means make the yard more square, and therefore diminish the rotatory momentum of this impulse, yet the impulse is more increased (by the theory) than its vertical lever is diminished.—Let us examine this a little more particularly, because it is reckoned one of the nicest points of seamanship to aid the ship's coming round by means of the headsails; and experienced seamen differ in their practice in this manœuvre. Suppose the yard braced up to 40°, which is as much as can be usually done, and that the sail shivers, (the bowlines are usually let go when the helm is put down), the sail immediately takes aback, and in a moment we may suppose an incidence of 6 degrees. The impulse corresponding to this is 400, (by experiment), and the cosine of 40° is 766. This gives 306 400 for the effective impulse. To proceed according to the theory, we should brace the yard to 70°, which would give the wind (now 34° on the weather-bow) an incidence of nearly 36°, and the sail an inclination of 20° to the intended motion, which is perpendicular to the keel. For the tangent of 20° is about $\frac{1}{2}$ of the tangent of 36°. Let us now see what effective impulse the experimental law of oblique impulsions will give for this adjustment of the sails. The experimental impulse for 36° is 480; the cosine of 70° is 342; the product is 164 160, not much exceeding the half of the former. Nay, the impulse for 36°, calculated by the theory, would have been only 346, and the effective impulse only 118 332. And it must be farther observed, that this theoretical adjustment would tend greatly to check the evolution, and in most cases would entirely mar it, by checking the ship's motion a-head, and consequently the action of the rudder, which is the most powerful agent in the evolution; for here would be a great impulse directed almost astern.

A nice point of seamanship.

We were justifiable, therefore, in saying, in the beginning of this article, that a seaman would frequently find himself baffled if he were to work a ship according to the rules deduced from M. Bouguer's work; and we see by this instance of what importance it is to have the oblique impulsions of fluids ascertained experimentally. The practice of the most experienced seamen is directly the opposite to this theoretical maxim, and its success greatly confirms the usefulness of these experiments of the academicians so often praised by us.

We return again to the general consideration of the rotatory motion. We found the velocity $v = \frac{F \cdot qG}{\int pr^2}$. It is therefore proportional, *cæteris paribus*, to qG. We have seen in what manner qG depends on the position and situation of the sail or rudder when the point G is fixed. But it also depends on the position of G. With respect to the action of the rudder, it is evident that it is so much the more powerful, as it is more remote from G. The distance from G may be increased either by moving the rudder farther aft or G farther forward. And as it is of the utmost importance that a ship answer her helm with the greatest promptitude, those circumstances have been attended to which distinguished fine steering ships from such as had not this quality; and it is in a great measure to be ascribed to this, that, in the gradual improvement of naval architecture, the centre of gravity has been placed far forward. Perhaps the notion of a centre of gravity did not come into the thoughts of the rude builders in early times; but they observed that those boats and ships steered best which had their extreme breadth before the middle point, and consequently the bows not so acute as the stern. This is so contrary to what one would expect, that it attracted attention more forcibly; and, being somewhat mysterious, it might prompt to attempts of improvement, by exceeding in this singular maxim. We believe that it has been carried as far as is compatible with other essential requisites in a ship.

Of impor ance to d termine th best place for a shi centre of gravity.

We believe that this is the chief circumstance in what is called the trim of a ship; and it were greatly to be wished that the best place for the centre of gravity could be accurately ascertained. A practice prevails, which is the opposite of what we are now advancing. It is usual to load a ship so that her keel is not horizontal, but lower abaft. This is found to improve her steerage. The reason of this is obvious. It increases the acting surface of the rudder, and allows the water to come at it with much greater freedom and regularity; and it generally diminishes the griping of the ship forward, by removing a part of the bows out of the water. It has not always this effect; for the form of the harping aloft is frequently such, that the tendency to gripe is diminished by immersing more of the bow in the water.

But waving these circumstances, and attending only to the rotatory energy of the rudder, we see that it is of advantage to carry the centre of gravity forward. The same advantage is gained to the action of the after sails. But, on the other hand, the action of the headsails is diminished by it; and we may call every sail a headsail whose centre of gravity is before the centre of gravity of the ship; that is, all the sails hoisted on the bowsprit and foremast, and the staysails hoisted on the mainmast; for the centre of gravity is seldom far before the mainmast.

Suppose that when the rudder is put into the position AD, (fig. 11), the centre of gravity could be shifted to g, so as to increase qG, and that this is done without increasing the sum of the products pr^2. It is obvious that the velocity of conversion will be increased in the proportion of qG to qg. This is very possible, by bringing to that side of the ship parts of her loading which were situated at a distance from G on the other side. Nay, we can make this change in such a manner that $\int pr^2$ shall even be less than it was before, by taking care that every thing which we shift shall be nearer to g than it was formerly to G. Suppose it all placed in one spot m, and that m is the quantity of matter so shifted, while M is the quantity of matter in the whole ship. It is only necessary that $m \cdot gG^2$ shall be less than the sum of the products pr^2, corresponding to the matter which has been shifted. Now, although the matter which is easily moveable is generally very small in comparison to the whole matter of the ship, and therefore can make but a small change in the place of the centre of gravity, it may frequently be brought from places so remote that it may occasion a very sensible diminution of the quantity $\int pr^2$, which expresses the whole momentum of inertia.

A practi of seame in puttin about explained.

This explains a practice of the seamen in small wherries or skiffs, who, in putting about, are accustomed to place themselves to leeward of the mast. They even find that they can aid the quick motions of these light boats by the way in which they rest on their two feet, sometimes leaning all on one foot, and sometimes on the other. And we have often seen this evolution very sensibly accelerated in a ship of war, by the crew running suddenly, as the helm is put down, to the lee-bow. And we heave heard it asserted by very expert seamen, that after all attempts to wear ship (after lying-to in a storm) have failed, they have succeeded by the crew collecting themselves near the weather fore-shrouds the moment the helm was put down. It must be agreeable to the reflecting seaman to see this practice supported by undoubted mechanical principles.

The evolution accelerated by additional matter.

It will appear paradoxical to say that the evolution may be accelerated even by an addition of matter to the ship; and though it is only a piece of curiosity, our readers may wish to be made sensible of it. Let m be the addition, placed in some point m lying beyond G from q. Let S be the spontaneous centre of conversion before the addition. Let v be the velocity of rotation round g, that is, the velocity of a point whose distance from g is 1, and let ϱ be the radius vector, or distance of a particle from g. We have (ROTATION, No. 22.) $v=\frac{F\cdot qg}{\int p\varrho^2+m\cdot mg^2}$. But we know (ROTATION, No. 23.) that $\int p\varrho^2=\int pr^2+M\cdot Gg^2$. Therefore $v=\frac{F\cdot qg}{\int pr^2+M\cdot Gg^2+m\cdot mg^2}$. Let us determine Gg and mg and qg.

Let mG be called z. Then, by the nature of the centre of gravity, $M+m:M=Gm:gm=z:gm$, and $gm=\frac{M}{M+m}z$, and $m\cdot gm^2=\frac{mM^2}{\overline{M+m})^2}z^2$. In like manner, $M\cdot Gg^2=\frac{Mm^2}{\overline{M+m})^2}z^2$. Now $mM^2+m^2M=Mm\times\overline{M+m}$. Therefore $M\cdot Gg^2+m\cdot gm^2=\frac{Mm\times(M+m)}{\overline{M+m})^2}z^2,=\frac{Mm}{M+m}z^2$. Let u be $=\frac{m}{M+m}$, then $M\cdot Gg^2+m\cdot gm^2=Mnz^2$. Also $Gg=nz$, being $=\frac{m}{M+n}z$. Let qG be called c: then $qg=c+nz$. Also let SG be called e.

We have now for the expression of the velocity $v=\frac{F(c+nz)}{\int pr^2+Mnz^2}$, or $v=\frac{F}{M}\times\frac{c+nz}{\frac{\int pr^2}{M}+nz^2}$. But (ROTATION, No. 30.) $\frac{\int pr^2}{M}=ce$. Therefore, finally, $v=\frac{F}{M}\times\frac{c+nz}{ce+nz^2}$. Had there been no addition of matter made, we should have had $v=\frac{F}{M}\times\frac{c}{ce}$. It remains to shew, that z may be so taken that $\frac{c}{ce}$ may be less than $\frac{c+nz}{ce+nz^2}$. Now, if c be to z as ce to z^2, that is, if z be taken equal to e, the two fractions will be equal. But if z be less than e, that is, if the additional matter is placed anywhere between S and G, the complex fraction will be greater than the fraction $\frac{c}{ce}$, and the velocity of rotation will be increased. There is a particular distance which will make it the greatest possible, namely, when z is made $=\frac{1}{n}(\sqrt{c^2+nce}-c)$, as will easily be found by treating the fraction $\frac{c+nz}{ce+nz^2}$, with z, considered as the variable quantity, for a maximum. In what we have been saying on this subject, we have considered the rotation only in as much as it is performed round the centre of gravity, although in every moment it is really performed round a spontaneous axis lying beyond that centre.

The rotation performed round a spontaneous axis.

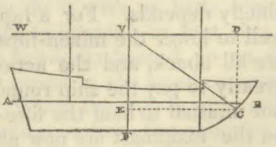
This was done because it afforded an easy investigation, and any angular motion round the centre of gravity is equal to the angular motion round any other point. Therefore the extent and the time of the evolution are accurately defined. From observing that the energy of the force F is proportional to qG, an inattentive reader will be apt to conceive the centre of gravity as the centre of motion, and the rotation as taking place, because the momenta of the sails and rudder, on the opposite sides of the centre of gravity, do not balance each other. But we must always keep in mind that this is not the cause of the rotation. The cause is the want of equilibrium round the point C, (fig. 10), where the actions of the water balance each other. During the evolution, which consists of a rotation combined with a progressive motion, this point C is continually shifting, and the unbalanced momenta which continue the rotation always respect the momentary situation of the point C. It is nevertheless always true, that the energy of a force F is proportional, *cæteris paribus*, to qG, and the rotation is always made in the same direction as if the point G were really the centre of conversion. Therefore the mainsail acts always (when oblique) by pushing the stern away from the wind, although it should sometimes act on a point of the vertical lever through C, which is a-head of C.

These observations on the effects of the sails and rudder in producing a conversion, are sufficient for enabling us to explain any case of their action which may occur. We have not considered the effects which they tend to produce by inclining the ship round a horizontal axis, viz. the motions of rolling and pitching. (See ROLLING and PITCHING.) To treat this subject properly would lead us into the whole doctrine of the equilibrium of floating bodies, and it would rather lead to maxims of construction than to maxims of manœuvre. M. Bouguer's *Traité du Navire* and Euler's *Scientia Navalis* are excellent performances on this subject, and we are not here obliged to have recourse to any erroneous theory.

Different operations of the water on the ship and wind on the sails balance each other.

It is easy to see that the lateral pressure both of the wind on the sails and of the water on the rudder tends to incline the ship to one side. The sails also tend to press the ship's bows into the water, and, if she were kept from advancing, would press them down considerably. But by the ship's motion, and the prominent form of her bows, the resistance of the water to the fore part of the ship produces a force which is directed upwards. The sails also have a small tendency to raise the ship, for they constitute a surface which in general separates from the plumb-line below. This is remarkably the case in the staysails, particularly the jib and fore-topmast staysail. And this helps greatly to soften the ship's bows into the head seas. The upward pressure also of the water on her bows, which we just now mentioned, has a great effect in opposing the immersion of the bows which the sails produce by acting on the long levers furnished by the masts. M. Bouguer gives the name of *point velique* to the point V (fig 12.) of the mast, where it is cut by the line CV ,which marks the mean place and direction of the whole impulse of the water on the bows. And he observes, that if the mean direction of all the actions of the wind on the sails be made to pass also through this

Fig. 12.



point, there will be a perfect equilibrium, and the ship will have no tendency to plunge into the water or to rise out of it; for the whole of the water on the bows, in the direction CV, is equivalent to, and may be resolved into the action CE, by which the progressive motion is resisted, and the vertical action CD, by which the ship is raised above the water. The force CE must be opposed by an equal force VD, exerted by the wind on the sails, and the force CD is opposed by the weight of the ship. If the mean effort of the sails passes above the point V, the ship's bow will be pressed into the water; and if it pass below V, her stern will be pressed down. But, by the union of these forces, she will rise and fall with the sea, keeping always in a parallel position. We apprehend that it is of very little moment to attend to the situation of this point. Except when the ship is right afore the wind, it is a thousand chances to one that the line CV of mean resistance does not pass through any mast; and the fact is, that the ship cannot be in a state of uniform motion on any other condition but the perfect union of the line of mean action of the sails, and the line of mean action of the resistance. But its place shifts by every change of leeway or of trim; and it is impossible to keep these lines in one constant point of intersection for a moment, on account of the incessant changes of the surface of the water on which she floats. M. Bouguer's observations on this point are, however, very ingenious and original.

Chief evolutions described.

We conclude this dissertation by describing some of the chief movements or evolutions. What we have said hitherto is intended for the instruction of the artist, by making him sensible of the mechanical procedure. The description is rather meant for the amusement of the landsman, enabling him to understand operations that are familiar to the seaman. The latter will perhaps smile at the awkward account given of his business by one who cannot hand, reef, or steer.

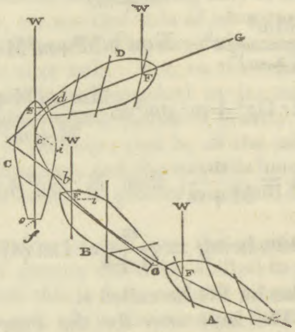
To tack Ship.

The ship must first be kept full, that is, with a very sensible angle of incidence on the sails, and by no means hugging the wind. For as the evolution is chiefly performed by the rudder, it is necessary to give the ship a good velocity. When the ship is observed to luff up of herself, that moment is to be catched for beginning the evolution, because she will by her inherent force continue this motion. The helm is then put down. When the officer calls out helm's a-lee, the fore-sheet, fore-top bowline, jib, and stay-sail sheets forward are let go. The jib is frequently hauled down. Thus the obstacles to the ship's head coming up to the wind by the action of the rudder are removed. If the mainsail is set, it is not unusual to clue up the weather side, which may be considered as a headsail, because it is before the centre of gravity. The mizen must be hauled out, and even the sail braced to windward. Its power in paying off the stern from the wind conspires with the action of the rudder. It is really an aerial rudder. The sails are immediately taken aback. In this state the effect of the mizen-topsail would be to obstruct the movement, by pressing the stern the contrary way to what it did before. It is therefore either immediately braced about sharp on the other tack, or lowered. Bracing it about evidently tends to pay round the stern from the wind, and thus assist in bringing the head up to the wind. But in this position it checks the progressive motion of the ship, on which the evolution chiefly depends. For a rapid evolution, therefore, it is as well to lower the mizen-topsail. Meantime, the headsails are all aback, and the action of the wind on them tends greatly to pay the ship round. To increase this effect, it is not unusual to haul the fore-top bowline again. The sails on the mainmast are now almost becalmed; and therefore when the wind is right a-head, or a little before, the mainsail is hauled round and braced up sharp on the other tack with all expedition. The staysail sheets are now shifted over to their places for the other tack. The ship is now entirely under the power of the headsails and of the rudder, and their actions conspire to promote the conversion. The ship has acquired an angular motion, and will preserve it, so that now the evolution is secured, and she falls off apace from the wind on the other tack. The farther action of the rudder is therefore unnecessary, and would even be prejudicial, by causing the ship to fall off too much from the wind before the sails can be shifted and trimmed for sailing on the other tack. It is therefore proper to right the helm when the wind is right a-head, that is, to bring the rudder into the direction of the keel. The ship continues her conversion by her inherent force and the action of the headsails.

When the ship has fallen off about four points from the wind, the headsails are hauled round, and trimmed sharp on the other tack with all expedition; and although this operation was begun with the wind four points on the bow, it will be six before the sails are braced up, and therefore the headsails will immediately fill. The after sails have filled already, while the head sails were inactive, therefore immediately check the farther falling off from the wind. All sails now draw, for the staysail sheets have been shifted over while they were becalmed or shaking in the wind. The ship now gathers way, and will obey the smallest motion of the helm to bring her close to the wind.

We have here supposed, that during all this operation the ship preserves her progressive motion. She must therefore have described a curve line, advancing all the way to windward. Fig. 13 is a representation of this evolution when it is performed in the completest manner. The ship standing on the course E *a*, with the wind blowing in the direction WF, has her helm put hard a-lee when she is in the position A. She immediately deviates from her course, and describing a curve, comes to the position B, with the wind blowing in the direction WF of the yards, and the square-sails now shiver. The mizen topsail is here represented braced sharp on the other tack, by which its tendency to aid the angular motion (while it checks the progressive motion) is distinctly seen. The main and foresails are now shivering, and immediately after are taken aback. The effect of this on the headsails is distinctly seen to be favourable to the conversion, by pushing the point F in the direction F*i*; but for the same reason it continues to retard the progressive motion. When the ship has attained to the position C, the mainsail is hauled round and trimmed for the other tack. The impulse in the direction F*i* still aids the conversion and retards the progressive motion. When the ship has attained a position between C and D, such that the main and mizen topsail yards are in the direction of the wind, there is nothing to counteract the force of the headsails to pay the ship's head off from the wind. Nay, during the progress of the ship to this intermediate position, if any wind gets at the main or mizen topsails, it acts on their anterior surfaces, and impels the after parts of the ship away from the curve *a b c d*, and thus aids the revolution. We have therefore said, that when once the sails are taken fully aback, and particularly when the wind is brought right ahead, it is scarce possible for the evolution to fail; as soon therefore as the main topsail (trimmed for the other tack) shivers, we are certain that

Fig. 13.



the headsails will be filled by the time they are hauled round and trimmed. The staysails are filled before this, because their sheets have been shifted, and they stand much sharper than the square-sails;[1] and thus every thing tends to check the falling off from the wind on the other tack, and this no sooner than it should be done. The ship immediately gathers way, and holds on in her new course dG.

But it frequently happens, that in this conversion the ship loses her whole progressive motion. This sometimes happens while the sails are shivering before they are taken fully aback. It is evident, that in this case there is little hope of success, for the ship now lies like a log, and neither sails nor rudder have any action. The ship drives to leeward like a log, and the water acting on the lee-side of the rudder checks a little the driving of the stern. The head therefore falls off again, and by and by the sails fill, and the ship continues on her former tack. This is called missing stays, and it is generally owing to the ship's having too little velocity at the beginning of the evolution. Hence the propriety of keeping the sails well filled for some little time before. Rough weather, too, by raising a wave which beats violently on the weather-bow, frequently checks the first luffing of the ship, and beats her off again.

If the ship lose all her motion after the headsails have been fully taken aback, and before we have brought the wind right ahead, the evolution becomes uncertain, but by no means desperate; for the action of the wind on the headsails will presently give her stern-way. Suppose this to happen when the ship is in the position C. Bring the helm over hard to windward, so that the rudder shall have the position represented by the small dotted line of. It is evident, that the resistance of the water to the stern-way of the rudder acts in a favourable direction, pushing the stern outward. In the mean time, the action of the wind on the headsails pushes the head in the opposite direction. These actions conspire therefore in promoting the evolution; and if the wind is right ahead, it cannot fail, but may even be completed speedily, because the ship gathers stern-way, and the action of the rudder becomes very powerful; and as soon as the wind comes on the formerly lee-bow, the action of the water on the now lee-quarter will greatly accelerate the conversion. When the wind therefore has once been brought nearly right ahead, there is no risk of being baffled.

But should the ship have lost all her headway considerably before this, the evolution is very uncertain; for the action of the water on the rudder may not be nearly equal to its contrary action on the lee-quarter; in which case, the action of the wind on the headsails may not be sufficient to make up the difference. When this is observed, when the ship goes astern without changing her position, we must immediately throw the headsails completely aback, and put the helm down again, which will pay off the ship's head from the wind enough to enable us to fill the sails again on the same tack, to try our fortune again; or we must boxhaul the ship in the manner to be described by and by.

Such is the ordinary process of tacking ship; a process in which all the different modes of action of the rudder and sails are employed. To execute this evolution in the most expeditious manner, and so as to gain as much on the wind as possible, is considered as the test of an expert seaman. We have described the process which is best calculated for *ensuring* the movement. But if the ship be sailing very briskly in smooth water, so that there is no danger of missing stays, we may gain more to windward considerably by keeping fast the fore-top bowline and the jib and stay-sail sheets till the square sails are all shivering. For these sails, continuing to draw with considerable force, and balancing each other tolerably fore and aft, keep up the ship's velocity very much, and thus maintain the power of the rudder. If we now let all fly when the square sails are shivering, the ship may be considered as without sails, but exposed to the action of the water on the lee-bow; from which arises a strong pressure of the bow to windward, which conspires with the action of the rudder to aid the conversion. It evidently leaves all that tendency of the bow to windward which arises from leeway, and even what was counteracted by the formerly unbalanced action of these head-staysails. This method lengthens the whole time of the evolution, but it advances the ship to windward. Observe, too, that keeping fast the foretop bowline till the sail shivers, and then letting it go, insures the taking aback of that sail, and thus instantly produces an action that is favourable to the evolution.

The most expert seamen, however, differ among themselves with respect to these two methods, and the first is the most generally practised in the British navy, because the least liable to fail. The forces which oppose the conversion are sooner removed, and the production of a favourable action by the backing of the foretop-sail is also sooner obtained, by letting go the foretop bowline at the first.

Having entered so minutely into the description and rationale of this evolution, we have sufficiently turned the reader's attention to the different actions which co-operate in producing the motions of conversion. We shall therefore be very brief in our description of the other evolutions.

To wear Ship.

When the seaman sees that his ship will not go about head to wind, but will miss stays, he must change his tack the other way; that is, by turning her head away from the wind, going a little way before the wind, and then hauling the wind on the other tack. This is called *wearing* or *veering* ship. It is most necessary in stormy weather with little sail, or in very faint breezes, or in a disabled ship.

The process is exceedingly simple; and the mere narration of the procedure is sufficient for showing the propriety of every part of it.

Watch for the moment of the ship's falling off, and then haul up the mainsail and mizen, and shiver the mizen topsail, and put the helm a-weather. When the ship falls off sensibly (and not before), let go the bowlines. Ease away the fore-sheet, raise the fore tack, and gather aft the weather fore-sheet, as the lee-sheet is eased away. Round in the weather-braces of the fore and main-masts, and keep the yards nearly bisecting the angle of the wind and keel, so that when the ship is before the wind the yards may be square. It may even be of advantage to round in the weather-braces of the main-topsail more than those of the headsails; for the mainmast is abaft the centre of gravity. All this while the mizen-top sail must be kept shivering, by rounding in the weather-braces as the ship pays off from the wind. Then the main-topsail will be braced up for the other tack by the time that we have brought the wind on the weather-quarter. After this it will be full, and will aid the evolution. When the wind is right aft, shift the jib and stay-sail sheets. The evolution now goes on with great rapidity; therefore briskly haul on board the fore and main tacks, and haul out the mizen, and set the mizen-staysail as they will take the wind the right way. We must now check the great rapidity with which the ship comes to the wind on the other tack, by righting the helm before we bring the wind on the beam; and all must be trimmed fore and aft by this time, that the headsails may take and check the coming-to. All being trimmed, stand on close by the wind.

We cannot help losing much ground in this movement. Therefore, though it be very simple, it requires much attention and rapid execution to do it with as little loss of ground as possible. One is apt to imagine at first that it would be better to keep the headsails braced up on the former tack, or at least not to round in the weather-braces so much as is here directed. When the ship is right afore the wind, we should expect assistance from the obliquity of the head-sails; but the rudder being the principal agent in the evolution, it is found that more is gained by increasing the ship's velocity, than by a smaller impulse in the headsails more favourably directed. Experienced seamen differ, however, in their practice in respect of this particular.

---

[1] The use of stay-sails has been almost entirely discontinued in the navy for some years. They are still supplied, however, and the fashion of using them will probably return after a time.

To box-haul a Ship.

This is a process performed only in critical situations, as when a rock, a ship, or some danger, is suddenly seen right a-head, or when a ship misses stays. It requires the most rapid execution.

The ship being close-hauled on a wind, haul up the mainsail and mizen, and shiver the top-sails, and put the helm hard a-lee altogether. Raise the fore-tack, let go the head bowlines, and brace about the headsails sharp on the other tack. The ship will quickly lose her way, get stern-way, and then fall off, by the joint action of the headsails and of the inverted rudder. When she has fallen off eight points, brace the aftersails square, which have hitherto been kept shivering. This will at first increase the power of the rudder, by increasing the stern-way; and at the same time it makes no opposition to the conversion which is going on. The continuation of her circular motion will presently cause them to take the wind on their after surfaces. This will check the stern-way, stop it, and give the ship a little headway. Now shift the helm, so that the rudder may again act, in conjunction with the headsails, in paying her off from the wind. This is the critical part of the evolution, because the ship has little or no way through the water, and will frequently remain long in this position. But as there are no counteracting forces the ship continues to fall off. Then the weather-braces of the after sails may be gently rounded in, so that the wind acting on their hinder surfaces may both push the ship a little a-head and her stern laterally in conjunction with the rudder. Thus the wind is brought upon the quarter, and the headsails shiver. By this time the ship has acquired some headway. A continuation of the rotation would now fill the headsails, and their action would be contrary to the intended evolution. They are therefore immediately braced the other way, nearly square, and the evolution is now completed in the same manner with wearing ship.

Some seamen brace all the sails aback the moment that the helm is put hard a-lee, but the after-sails no more aback than just to square the yards. This quickly gives the ship stern-way, and brings the rudder into action in its inverted direction; and they think that the evolution is accelerated by this method.

There is another problem of seamanship deserving of our attention, which cannot properly be called an evolution. This is lying-to. This is done in general by laying some sails aback, so as to stop the head-way produced by others. But there is a considerable address necessary for doing this in such a way that the ship shall lie easily, and under command, ready to proceed in her course, and easily brought under weigh.

To bring-to with the fore or main topsail to the mast, brace that sail sharp aback, haul out the mizen, and clap the helm hard a-lee.

Suppose the fore topsail to be aback; the other sails shoot the ship a-head, and the lee-helm makes the ship come up to the wind, which makes it come more perpendicularly on the sail which is aback. Then its impulse soon exceeds those on the other sails which are now shivering, or almost shivering. The ship stands still awhile, and then falls off, so as to fill the after sails, which again shoot her a-head, and the process is thus repeated. A ship lying-to in this way goes a good deal a-head and also to leeward. If the main topsail be aback, the ship shoots a-head, and comes up till the diminished impulse of the drawing sails in the direction of the keel is balanced by the increased impulse on the main-topsail. She lies a long while in this position, driving slowly to leeward; and she at last falls off by the beating of the water on her weather-bow. She falls off but little, and soon comes up again.

Thus a ship lying-to is not like a mere log, but has a certain motion which keeps her under command. To get under weigh again, we must watch the time of falling off; and when this is just about to finish, brace about briskly, and fill the sail which was aback. To aid this operation, the jib and fore-topmast stay-sail may be hoisted, and the mizen brailed up; or, when the intended course is before the wind or large, back the fore-topsail sharp, shiver the main and mizen topsail, brail up the mizen, and hoist the jib and fore-topmast staysails altogether.

In a storm with a contrary wind, or on a lee shore, a ship is obliged to lie-to under a very low sail. Some sail is absolutely necessary, in order to keep the ship steadily down, otherwise she would kick about like a cork, and roll so deep as to strain and work herself to pieces. Different ships behave best under different sails. In a very violent gale, the three lower stay-sails are in general well adapted for keeping her steady, and distributing the strain. This mode seems also well adapted for wearing, which may be done by hauling down the mizen-staysail. Under whatever sail the ship is brought-to in a storm, it is always with a filled sail, and never with one laid aback. The helm is lashed down hard a-lee; and therefore the ship shoots a-head, and comes up till the sea on her weather-bow beats her off again. Getting under weigh is generally difficult; because the ship and rigging are lofty abaft, and hinder her from falling off readily when the helm is put hard a-weather. We must watch the falling off, and assist the ship by some small headsail. Sometimes the crew get up on the weather fore-shrouds in a crowd, and thus present a surface to the wind.

These examples of the three chief evolutions will enable those who are not seamen to understand the propriety of the different steps, and also to understand the other evolutions as they are described by practical authors. We are not acquainted with any performance in our language, where the whole are considered in a connected and systematic manner. There is a book on this subject in French, called *Le Manœuvrier*, by M. Bourdé de Ville-Huet, which is in great reputation in France.

We offer this account of the subject with all proper respect and diffidence. We do no profess to teach; but by pointing out the defects of the celebrated work of M. Bouguer, and the course which may be taken to remove them, while we preserve much valuable knowledge which they contain, we may perhaps excite some persons to apply to this subject, who, by a combination of what is just in M. Bouguer's theory, with an experimental doctrine of the impulses of fluids, may produce a treatise of seamanship which will not be confined to the libraries of mathematicians, but become a manual for seamen by profession.[1] (B.B.B.)

---

[1] There are several good treatises on seamanship in English; but we think the whole topic has become of sufficient importance to deserve still more literary attention than it has yet received; and we are persuaded that a well-digested, and well written marine dictionary, scientific, practical, and popular, if sufficiently copious, and undertaken by a competent hand, would be considered a great boon, not only to seamen, but to the society at large of this essentially maritime country. The most approved works on seamanship in English are the following: Falconer's Marine Dictionary; Darcy Lever's Seamanship; Theory and Practice of Seamanship, by Richard Hall Gower; Griffith's Practical Hints; Nicholson's Seamanship; Steel's Elements and Practice of Rigging, Seamanship, and Naval Tactics. The most recent works on Seamanship with which we are acquainted, are the following: Captain Glascock's Naval Officer's Manual; Lieutenant Martelli's Naval Officer's Guide, and Lieutenant Fordyce's Outlines of Naval Routine. Many useful practical hints may also be derived from the perusal of James's Naval History. The best foreign writers on Seamanship and Tactics, are Pere Hoste, Morogues, Byland, Bourdé, Lescallier, and Grenier.

The foregoing article having been written by the celebrated Professor John Robison, it has been thought proper to reprint it exactly as it left his hands, with the addition of one or two notes explanatory of circumstances which the lapse of time has rendered obscure. This course has been adopted chiefly out of deference to the high authority of the author, which must render it a measure of questionable propriety to retouch, or otherwise alter, or try to improve, an essay which, at the time it was written, must have been considered as complete. But the interests of the readers of this Encyclopædia have also, it is believed, been considered in this matter, since any additions or interpolations made in an article composed with the care which marks every thing from the pen of Professor Robison, might so materially have altered the texture of the fabric, as to divest it of much of its beauty as well as utility. We have, indeed, the means of knowing that the article, as it stands, has been of extensive practical utility; and every admirer of simple, and at the same time vigorous writing, clear and straight to the purpose, must be well pleased to know that no attempt has been made to improve a style which is matchless.

At the same time it is manifest, upon a moment's reflection, that even the most general view of such an art as Seamanship, written more than forty years ago, cannot possibly include many things which it is material should be adverted to. This science, as it may now fairly be called, has greatly advanced within that period. With the improvements which have been made in most other departments of industry and knowledge, the public are more or less familiar, and great pains have been taken throughout this work to extend that familiarity by such popular explanations as shall not only be intelligible to general readers, but be useful to those whom pleasure or business inclines to go deeper. But the art or science of Seamanship, call it which we please, has certainly been too much kept out of sight of late years; and it is the purpose of this Appendix to supply, in a brief space, the deficiency complained of by many persons, whose habits entirely unfit them for gaining the knowledge for themselves, and yet, who are perfectly competent to understand, as well as to appreciate, the value of such information, when stated in clear language.

Most other sciences may be studied with effect in the closet. An amateur astronomer, for example, or a chemist, furnished with good instruments, and having confidence in the skill and good faith of the leaders in the particular walk of knowledge to which his taste inclines him, may, by adopting their results, pursue the same paths with almost equal profit, and perhaps with more pleasure than those who take all the labour, and incur all the responsibility. But there is no royal road of this sort, by which an amateur sailor can investigate the results of seamanship, the mysteries of which, to be fully understood, must be studied afloat, at sea, in all weathers, and in every climate.

All the world, however, knows that the results of nautical skill and exertion are not the same as they used to be. A voyage to India and back, in former times, occupied a couple of years, or more; it is now currently done in nine months, even by ordinary merchant vessels, including the time taken to unload and reload their cargoes. In former days, the scurvy struck down half the crew of every ship which made a long voyage, and was even fearfully prevalent in the navy; now the disease is almost unknown. The numbers of all kinds of ships afloat have enormously increased, and the war of the elements by which they were formerly assailed is no less violent than it was; but assuredly a far smaller proportion of vessels are now driven on shore than were formerly wrecked. The comforts, too, of travelling by sea, in the articles of provisions and water, are all essentially improved; and, finally, the security, as well as the happiness of all persons on board, whether passengers or crew, has been marvellously augmented by the general establishment of a better system of discipline than was known in bygone days; whilst many old manipulations of seamanship are so modified by new contrivances, that if old Benbow, or even Kempenfelt, were to arise from the dead, he would scarcely know how to handle his ship.

It may not be without use, and it certainly must be interesting, to those who have not studied such things personally, to see by an example how scientific seamanship is made to triumph over that groping and blundering method of navigating ships which is technically known by the name of the "rule of thumb." If we take a globe, and trace on it the shortest route, by sea, to India, and then fancy that such must be the best course to follow, we shall be very much mistaken. And yet this is very much what our ancestors actually did, till time, and repeated trials, and multitudinous failures, gradually taught them where to seek for winds, and how to profit by them when found. According to the "rule of thumb" sailing, a ship had only to steer from England to Madeira, pass the Canaries and Cape de Verds, and then to make a direct course to the Cape, and thence to India. On trial, however, this experiment always failed; for on getting near the equator, a series of calms and squalls put a stop to this straight-line scheme, and the mariners of old were then forced to toil along the coast of Africa, or were driven towards that of the Brazils, and very often they came back in utter hopelessness. Now-a-days, the exact spot where the north-east trade wind, which prevails in the northern Atlantic, ought to be parted with; in what district the calms and variables are most easily managed; over what degree of longitude on the equator the ship should pass; and, finally, in what place the south-east trade wind of the southern Atlantic is to be found, and how it is to be made most use of when found; are all matters of such familiarity to the really qualified navigator, that they scarcely occupy his thoughts, but are acted upon as matters of course, and, unless some unforeseen accident occurs, absolutely ensure the success of his voyage. The line he follows, however, is by no means the straight one which an ill-informed person would naturally have chalked out for him to follow, ignorant of the impossibility of pursuing it.

The modern navigator, by not seeking to husband the south-east trade wind too much, but by freely "flanking" through it, sweeps past the coast of Brazil, and by boldly dashing down into pretty high south latitudes, is certain, or almost certain, of finding there such a vein of westerly wind, as amply compensates for the apparent roundabout he has made in his course. In like manner, after passing the Cape, which to the old navigators was truly a "Cabo de tormentos," instead of vainly trying to reach India, by steering straight through the Mozambique channel, the scientific navigator, disregarding the increase of distance, maintains his position in a high latitude, and sails resolutely along a parallel of latitude, with the wind in his poop, till he has obtained such a degree of easting, that, on hauling up to the northward, and making for the south-east trade wind, he enters that mysterious aërial current on such terms as ensure his making it serve his purpose. If, however, he be timid or impatient by nature, and not duly instructed by experience, he will be very apt to haul up too soon to the northward, from not liking to run, as it appears, so far past his port. The consequence will be, that when he encounters the south-east trade-wind, he will find, that instead of its being fair, it is blowing in his teeth, and he will have to run back again to the southward to borrow a little more easting from the westerly breezes which prevail there.

Be it observed, however, that the above instructions would lead a seaman into great error, were he to make the rule absolute; for, at certain seasons of the year, that is, when the sun is far to the north of the line, and the south-west monsoon blowing in the Indian ocean, his course from the

Cape to India would lead him between Madagascar and the main land of Africa; and so he would sail across the equator, and enter the Bay of Bengal with a flowing sheet. At other seasons, so far from having a flowing sheet on reaching India, he may have to beat up the bay, "hank for hank," unless he has knowledge enough to know at which side to enter it, and skill enough,—for it requires a good deal,—to know how to profit by the land and sea breezes of the coasts respectively of Coromandel and of Pegu.

In short, not to swell this example too far, the truly scientific navigator, possessed of the requisite nautical instruments, (the most important of which we propose to speak of by and by), by which means he may at all times be certain of his place, may almost command a fair wind at every stage of his voyage, and thus secure his passage within a certain number of days; though, in his way, he will have had to vary his course a hundred times from that which, at first sight, might have been thought the best, merely because, on the map, it seemed the shortest. The old proverb, indeed, which warns us that the longest way about is often the shortest way home, has perhaps its amplest illustration in the practice of modern seamanship; but, let it be always borne in mind, that this is true only when all the varying circumstances of time and place are duly taken into account, and so appropriated as to give to the ship those advantages of fair wind and moderate weather, without which no voyage can be securely or speedily made. This branch of seamanship, therefore, more than any other, requires for its successful exercise a singular combination of the widest generalizations in theory, with the most minute and specific disintegrations of scientific research in practice. In the Indian seas especially, the whole history of the winds, examined without some theoretical clue, is a mass of confusion; and yet the profoundest meteorological science would inevitably prove not only useless, but absolutely dangerous to the navigator who should trust to it alone, without the aid of local information, and of the improvements of modern art.

These remarkable improvements are due to the spread of knowledge over the sea, as well as over the land; and it is proposed here, to examine a few of the causes which have led to such valuable results in the practice of seamanship, as they will all be found to fall readily under that great head. For detailed practical information, of a kind which might be useful to a sailor in the actual working of a ship, we must of course refer to the precise heads which treat professedly of these things, such as Anchors, Astronomy, Cables, Capstan, Navigation, Rope, Ship-building, Steam-Vessels, and so forth, the purpose of this Appendix to the article Seamanship being merely to point out, in a very general, but by no means superficial manner, the most important improvements which have been introduced afloat since the preceding article was written.

It will not be expected that much should be said here of the mighty revolution in nautical affairs brought about by the introduction of steam; for that subject demands, and has received the fullest attention in its proper place. We shall merely observe, that steam does not essentially interfere with seamanship proper, almost all the manipulations of which remain as before; whilst steam navigation, in spite of its boasted contempt of wind and tide, is still obliged to borrow so much from seamanship to complete its success, that without its aid it would often be useless, and even dangerous in the highest degree. We shall take occasion as we go along, to point out some of the most remarkable occasions in which the old system of seamanship proper is essential to the method by steam; merely remarking at present, that nearly all that branch of our subject which relates to navigation, that is, to the method by which a ship's place is determined at sea, the proper course shaped, and the different ports of the world recognised and made use of, remains the same. Latitudes and longitudes, and the variation of the compass, are evidently just as important to a steam vessel as to a sailing one; and though winds and currents are not quite so essential, every one who has made a steam voyage of any length, is aware how materially its celerity depends upon a knowledge of and due attention to these particulars. It is one of the chief points of a seaman's duty to know where to find a fair wind, and where to fall in with a favourable current; but the obligation, if not equally binding on a steam navigator, is almost so, when his voyage is a long one. The most remarkable occasions on which steam has the advantage over sails are, in a calm, and when the wind is directly ahead. In a calm, a sailing ship is utterly helpless, and must stand stock still; with a wind in her teeth, if it blow hard, she can do nothing, or does worse than nothing, drifts away from her point. There is another important occasion on which a steam vessel, if properly handled, has a wonderful advantage over an ordinary ship, and we advert to it, first, because we do not remember to have seen it mentioned before; and, secondly, because it involves some considerations of true seamanship, which it is the business of this Appendix to dwell on.

We allude to the formidable danger of a lee shore, in a gale of wind, when we shall suppose the weather to be such that a ship and a steam vessel are both obliged to anchor, and that from the anchor not holding, or the insufficient strength of the cables, there is risk of their being forced on the shore. In this predicament, we have heard of a steam vessel, by the mere agency of her steam, not exerted to any great extent, either keeping her cable slack, or very materially relieving it from the strain produced by the wind. But even supposing her stock of fuel expended, or that her machinery had got out of order, she may still be looked upon as a ship with her masts cut away, which, we may explain to unprofessional readers, is the most favourable condition for a ship to be in, under such dangerous circumstances. It may be asked, and with great reason, why, if this be so, should not the ship when in danger of driving on the rocks, also get rid of her masts, by cutting them away, and so place herself in as favourable a position as the steamer, on the lee shore? To this we answer, that the operation of cutting away the masts is always a very serious one, and, like the amputation of a limb to a labouring man, is not to be resorted to till the last extremity. Besides, it is often a matter of doubt, which is the last moment of safety, and the first of extreme danger; and as the commander of the ship may not have had experience of such critical cases, he may, and too often does, hesitate to dismember his vessel, till the anchor comes so rapidly home, that cutting away the masts will not stop her headlong way amongst the breakers; and then it is too late. The steam vessel, however, is *already*, and at all times, in the best condition for anchoring on a lee shore. We ought here to mention to our unnautical readers, in what consists the advantage of cutting away the masts, when a ship is in this situation, and is in danger, from the violence of the wind, of being drifted on the rocks. It is well known that the mere hull of a ship, placed with the bow to the wind, offers but a small resistance to the wind, compared to what is presented by the masts, yards, ropes, and sails; for though the sails be furled, they are generally, on such occasions, but clumsily handed, and hold much wind. The form of a ship's bow is equally adapted, or nearly so, to passing through the air as through the water, and the area offered by it to the wind is very small, compared to that which the "top hamper," as it is called, presents. Let any one in a gale of wind on board ship take hold of the smallest rope, the signal haulyards, for example, and he will find it requires a considerable exertion of his strength to prevent its being blown out of his grasp, and in proportion as the rope is large, so is the violence of the wind upon it. And when the immense number, and great length of the whole ropes of a ship are taken into account, to say nothing of the resistance of the lower masts and top-masts, and the yards, however sharply braced to the wind, we shall be satisfied that the resistance aloft is many fold greater than that which the hull alone offers to the wind. Accordingly, the prodigious additional security which is imparted to a ship on a lee shore by cutting away the masts, is well known to practical seamen. This conviction, resting on the ever energetic mind of Nelson, though within a few minutes of his last breath, was the true source of the last order he ever gave, "Hardy, anchor the fleet."

Whilst speaking of the comparative merits of steam vessels and ordinary ships under a stress of weather, it may be mentioned, that as steamers are furnished with very reduced masts and yards, they are in the most favourable position for making sail in a gale of wind, should sailing then be possible. In other words, a sea-going steamer, though comparatively much undermasted, is enabled, in a storm, to spread quite as much canvas as could be carried with advantage, in a sailing ship of her size, at that particular moment. It must be remembered, that the sailing vessel, in order to be able to make way in fine weather, is obliged at all times to carry with her, and to expose permanently aloft, an extent of masts and yards which is very detrimental to her progress in bad weather; whilst, on the other hand, the steamer stows away her fine weather power under hatches in her coal boxes, till the time returns when it can be used with advantage.

To return to the improvements introduced into the art of seamanship by the skill and science of late years, we may begin by adverting to the remarkable advantages which have been gained by the extensive use of iron on board ship.

In the year 1808, Captain Brown of the navy proposed the use of iron cables and rigging; but it was not till 1811 that the cables were fairly tried. They have since been used universally, and no greater boon was ever bestowed upon the sea service. The original cost of a chain cable is not much more than that of a hempen one, whilst its durability is greater, in a ratio which cannot be stated in figures. The security afforded by it is vastly greater; for it is exposed to none of the deteriorating causes which render a hempen cable, after much use, comparatively so little trust-worthy. The alternate wetting and drying, which saps the strength of a hempen cable, has no effect on one of iron. The friction against rocks, especially against coral, is often fatal to a hemp cable in a few minutes; but the same friction, after weeks of hard use, only slightly polishes a few links of the chain. In tropical countries, therefore, the introduction of chain cables has increased the security of ships at anchor tenfold; but in every climate their advantage is immense. Nor does this advantage consist solely in their strength and durability, for they are managed with much more facility, occupy far less space, and are coiled away with little, or it may be said, no trouble at all; for as they are hove in, they fall quietly into, and adjust themselves, in a box or case near the hatchway, from which they are drawn up when wanted with comparatively small labour. To those who remember the toil and trouble of "forming a bend" in the cable tier, the wet and the dirt, and the noise made by the numbers of men required to coil it away, these advantages will not be considered as small ones.

Several adaptations have been found necessary in consequence of the use of chain cables. The hawse holes require to be filled with strong cases, or tubes of iron; and a most ingenious and powerful stopper has been contrived by the late great and good Sir Thomas Hardy, (the ablest seaman we probably ever had in this country of seamen), by which the cable can at any time be prevented from running out, whatever be the strain upon it. This stopper consists of a large swan-necked bar of tough iron, which embraces the cable as it comes up the hatchway, having one of the ends of the curve fixed to the beams of the lower deck, by means of a powerful bolt, whilst to the other end is attached a tackle, also worked on the lower deck, by which this curved stopper can be drawn tight, and the chain pressed so firmly in its embrace, against the angle of the hatchway, that however quickly it may have been running out, or whatever strain may be brought on it, the cable is arrested almost immediately.

Iron cables require a peculiar but easily-learned description of management. They cannot, for example, be used in deep water, without some modification; for their weight, added to that of the anchor, is so great, that the labour of heaving up becomes prodigious. To remedy this evil, and yet to profit by the security which belongs to rendering invulnerable that part of the cable most exposed to friction by rocks, a device was suggested by admiral the Honourable George Elliot, which having been found to answer the purpose, is now generally adopted. An eye, with a thimble in it, is formed at the end of a hempen cable, and to this is shackled, in the usual way, one of the lengths of the chain. The outer end of this length of chain being then shackled to the anchor, the cable may be used in any depth of water, with nearly as much security as if it were made of iron from end to end, and with only the inconvenience arising from the additional weight of one length of chain. Another device has lately been introduced, which many seamen prefer. This consists of three-tapered tails of small chain, shackled to the main one, by which it can be spliced with ease and security to the hempen cable, with the strands of which it is "married" in the usual way. One advantage of chain cables is, that a ship may often lie at single anchor, without risk of fouling the anchor. If the scope of chain be too short, the tides strong, and the ground either of sand or of smooth and hard materials, there will be nearly the same risk of fouling the anchor as with a hempen cable; but if the scope be long, the tides not very impetuous, and, above all, if the ground consist of mud, there is scarcely any chance of this troublesome and dangerous accident happening. It may be proper to explain, that "fouling the anchor" means the entanglement of the cable with its flukes, or other parts, by which its power of holding the ground is destroyed, or so materially lessened, that when a strain is brought on it, the anchor slides along the bottom, and consequently the ship is no longer held firmly.

Any one who looks at an anchor will perceive that it consists of three principal parts, lying at right angles to one another. 1st, The arms or *flukes*, which form a sort of half-moon, from the *crown* or middle point of which springs; 2d, the *shank*, a long, straight, and very strong bar of iron, firmly welded to the crown at one end; whilst the other is passed through, and is firmly, grasped by the 3d part, viz., a stout beam of wood, called the *stock*. The end of the shank, which projects several inches beyond the stock, is fitted with a strong shackle, (formerly with a ring, when hemp only was used), to which the chain is attached. As long as the cable pulls the anchor by means of this shackle at the end of the shank, the anchor does its duty, and resists the effort to move it along the ground; and if the bottom be soft, the strain of the cable has even the effect of making the bill, or point of the lower fluke bury itself more and more deeply. The purpose of the stock, or long wooden beam which crosses the shank, is to force the anchor to assume its proper position, or that best adapted to its digging one of its flukes into the ground. This important purpose is effected by the tendency which the stock has to lie flat, that is, horizontally on the ground; a position, it will be observed, necessarily implying that one of the flukes is up, and the other buried beneath the surface of the bottom; so that if, by accident, the anchor, when first let go from the ship's bows, should rest on the ground with one end of the stock sticking up, and the other down, which would bring the flukes flat, or horizontally on the bottom, a position in which they would have no hold whatever, a slight strain on the cable puts all to rights, by tumbling the anchor over, so as to bring the stock into its true position, namely, flat on the ground, and of course the flukes upright. This tendency is the obvious consequence of the stock being so much longer across than the flukes are, which naturally causes the anchor to tumble over into its right position, whenever the stock is not lying flat, as it ought always to do.

For many years after the introduction of chain cables, hempen messengers were used to heave them in; now chains are almost universally used, and a great expense saved. The messenger is the endless rope which passes round the capstan, and being attached to the cable by what are well called nippers, draws in the cable along with it as the capstan is hove round. Iron nippers, too, must soon become universal. Chain slings for the lower yards have long been in use, and of late years chain topsail sheets, and chain ties, have been introduced, as well as chain gammoning for the bowsprit, and chain bobstays, which are great improvements.

Attempts are now making, and we feel convinced that they will ere long succeed, to introduce iron *wire* rigging, which we consider as stronger and better than chain, because less dependent on the accidental quality, and careless manufacture of a single part. And here we cannot help remarking, how strange it is that the plan of making iron bridges of wire, so successfully adopted in Switzerland, France, and elsewhere abroad, should not yet have found such favour in England as to be fairly tried. The noble bridge of Freyburg in Switzerland, is several hundred feet wider than the Menai bridge, and though it consists of but one span, it is equally strong, if not stronger, and has cost not a fifth part of the money. We do not think wire will answer for running rope; but for standing rigging it may, we conceive, be most usefully substituted for hemp.

The use of iron ballast, instead of dirty shingle, is also a recent, but valuable improvement, and though the first cost is greater, it very soon overpays itself. Iron ballast was first officially established in the navy about the year 1796.

The next most important use of iron is in a department of seamanship which is by no means to be lightly treated of, we mean the watering and provisioning of ships. The introduction of iron tanks into the navy and merchant service has in many ships doubled, and in all very greatly increased, the quantity of water which can be carried to sea; whilst the quality has been improved in a manner, of the extent and blessing of which no one can form an idea, unless he carries in his recollection the filthy stuff which it was so often the lot of seamen to drink in bygone days. The following statement shews, in a rough way, the gain of stowage.

The cask called a butt occupies about 35 cubic feet of space in a ship's hold, and this space, if it were entirely filled with water, would contain 217 gallons. A butt, however, actually holds only 108 gallons, so that one-half of the space is lost by the thickness, and by the form of the cask, which is the worst possible for stowage, so far as room is concerned. An iron tank, of the largest kind at present made for ships of war, is called a four-feet cube, though it measures about an inch more in its external dimensions, and occupies 68 cubic feet of space. This area, if entirely filled with water, would contain 424 gallons, but it actually holds 400, which is only 24 gallons less than the space could possibly contain. In other words, by using casks, you lose eight-seventeenths, or nearly a half, of the stowage room, whilst by using tanks you lose only one-seventeenth.

A farther increase in the stowage of water is gained by having iron tanks made either of a wedge, or of a flat form, to suit the curve of the ship's hold, or to enter spaces too low to receive cubical tanks.

A single example of the change which took place in a line-of-battle ship, will shew the gain effected by employing iron tanks instead of casks. The Melville, of 74 guns, when fitted with casks, stowed, of water, 47,624 gallons, or $212\frac{1}{2}$ tons. But when iron tanks were substituted, she stowed 88,232 gallons, or 394 tons, or about four-fifths more water. Thus, if the Melville, with a crew say of 600 men, at a gallon of water each per day, could keep the sea for only 80 days, or not quite *three* months, if it were kept in casks, she might carry, at full allowance, 147 days water, or very nearly *five* months, if it were stowed in iron tanks.

We have recently heard of some ships in which the bread, and other dry provisions, were stowed in iron tanks, with great advantage, not only in respect to stowage, but in preserving the provisions from decay. In hot and damp climates this becomes a primary consideration; and we know of a ship of war which, during the long and arduous campaign against the Burmese, by keeping her dry provisions in tanks, effectually excluded from the air, preserved the whole of her bread, flour, pease, cocoa, and rice, in the most perfect condition; whilst in most of the other vessels a large proportion of all the dry provisions were either decayed and rendered useless, or were eaten up by weavels and cockroaches, in spite of every care, greatly to the inconvenience of the public service.

This recalls to our recollection the preserved meats, soups, and vegetables, in cylindrical tin cases, first devised, we believe, by M. Appert, a Frenchman, and now in general use at sea. These meats are expensive, no doubt, but in the long run they often prove not so costly as live stock, because they eat and drink nothing. In all her Majesty's ships, these preserved meats have long been supplied to the sick; and we are of opinion it would be sound economy to serve them out once or twice a-week to the ship's companies generally.

The next most material change for the better, to which it is our duty to advert, in speaking of seamanship in the most extensive sense of that word, relates to the manner in which all ships are now navigated from port to port, and to and from the most distant parts of the globe, not only with far greater celerity, but with much greater safety than formerly. This truly wonderful improvement which has of late years been introduced into the art of seamanship, in shortening voyages, and adding to their security, as well as certainty, is due, mainly, first, to the superior knowledge of the persons in charge of ships; secondly, to the improved quality, lower cost, and greatly increased number of scientific instruments and astronomical tables, now in the hands of every seamanlike officer; thirdly, to the numbers, accuracy, and cheapness of the charts of almost all the navigable regions of the globe; and, lastly, to the more extensive and correct knowledge of the phenomena of the winds, weather, currents, and tides of the ocean. To these vast helps, which every sailor may now avail himself of, almost mechanically, there may be added others which those only can profit by, who, to long experience, add a taste for science, which not only sharpens the observation, but enables an expert navigator to appropriate to the purposes of his voyage, the thousand and one variations to which the elements are subject, but which no books, no rules, nor even talents, can effectually teach the mere seaman how to apply. Nothing, indeed, is more difficult in the practice of this branch of seamanship, than removing from the mind of an old sailor erroneous impressions as to fact, even when substantial means of correction are lying on his table. The truth is, the navigable world is so wide, the phenomena of nature so grand and varied, that until we are schooled by actual experience, we have not the means of grasping a sufficient number of observations at once, to enable us to generalise them into a practical shape, in the complicated art of seamanship.

In the first rank of modern instruments used at sea, stands the Sextant, not the old wooden quadrant of our grandfathers, and even some of our fathers in the art, but the brass sextant of Troughton, Dollond, or Cary, divided to ten seconds, and capable of taking lunar distances with precision. With such an instrument in his hands, and with such a nautical almanac as ours now is, there is no magician in fairy tale, who could cope with a well-practised seaman in the performance of miracles. What human feat, we will ask, can exceed in wonder the exact determination of a ship's place in the midst of a boundless ocean, a thousand miles from land? This marvellous quality of exactness, or rather, we should say, of infallibility, within certain appreciable limits, distinguishes the Sextant from all other nautical instruments. Its operations are connected with those of the sun, moon, and stars, and, by the nature of its construction, partake of their certainty; whereas the Chronometer, which stands the next in order of importance, is essentially a fallible instrument, and, though eminently useful in the navigation branch of seamanship, and much more nice in its determinations, can never be depended on as the Sextant can. These two instruments are admirable allies, but neither is sufficient, if used without the other, to meet the wants of modern navigation. A Chronometer may, and often does, change its rate, and thus it may deceive, instead of instructing, the mariner, without his having any suspicion of its misleading him, and though the chances of its doing so without detection are much lessened, by adding two or three more chronometers, still there never can be any certainty in the results. On the other hand, the errors of a Sextant lie all within the reach of detection and appreciation. They cannot, it is true, theoretically speaking, be fully corrected, yet they may be sufficiently compensated for in practice, which is all the seaman need care about. A single illustration will make this plain, even to those who have not attended to such subjects.

The longitude is found by measuring with a Sextant the angular distance between the moon and a star; and if the instrument used were perfectly correct in all its adjustments, true in its centering and its graduations, and the distance were properly observed, the result would be quite correct. But experience proves that every instrument, even after all the adjustments have been made as carefully as possible, does, in fact, measure the angle either too great or too small; and, consequently, the longitude which results from it will inevitably be too far east or too far west. The manner in which this evil is got rid of, is as follows. If the ship be in west longitude, and star observed lie to the *eastward* of the moon, and the sextant measures the angular distance *greater* than the truth, the resulting longitude will be less than the truth. If another star be now observed, lying to the *westward* of the moon, and the same instrument is used, the distance will, as before, be measured *greater* than the truth, but the resulting longitude will in this case be just as much *greater* than the truth, as the first result was *less;* but the mean of the two will of course be near the true longitude. By using a Sextant in this manner, and by taking a sufficient number of observations on both sides of the moon, when the distances are nearly the same, so close an approximation may be made to the true longitude, that not only may the ship's place be found near enough to steer by, but the errors in the rates of the Chronometers on board may be ascertained, and a fresh departure be taken, with nearly as much confidence as if a well-known headland had been seen. For all short voyages, such as those between port and port in the same country, Chronometers may be pretty confidently reckoned on, since the chances of their varying from their previously ascertained rates, in the course of a few days, are proportionally small. In like manner, the intermediate short runs made by the agency of the Chronometers, between lunar and lunar taken at sea, may be relied upon in practice.

Our neighbours the French, who are excellent navigators, use the reflecting and repeating circle much more than we do; but we have no hesitation in recommending the Sextant as much the superior instrument of the two for real work. Theoretically, no doubt, the circle is more perfect; but it has disadvantages which, after very long experience, we confidently affirm, render it less useful to a seaman than the sextant. In the first place, its weight, and above all, the surface it offers to the wind, render it more fatiguing to use, especially in bad weather. In the next place, its radius being much shorter than that of a sextant, the divisions on the limb are far less easily read off; a serious objection to the use of a circle at night, when every practised seaman knows that the best work in lunars is always done. If Troughton's circle with three verniers be used, which implies six readings for every complete observation, the labour is highly irksome; but even if the repeating circle be used, the risk of error, by the nicety of the manipulations, and the uncertainty of the adjustments, are, we have always found, an overmatch for the simplicity of the single reading off at the end. In short, we are sure that under the troublesome variety of circumstances which are to be encountered at sea, a well practised navigator, with a sextant in his hand, will do twice as much good work in a given time, as he could do with any description of circle which we have had the good fortune to use. On shore, indeed, the circle may often be used with greater effect; but our present purpose is to treat of seamanship.

The next in order of importance in the list of nautical instruments, after the Sextant, is the Chronometer; an instrument to which modern seamanship is indebted for very great service. We are old enough to remember when Chronometers were not only not in general use, but were rarely employed except on voyages expressly scientific. It is difficult to describe the degree of mortification, we may almost call it grief and indignation, with which practical men, skilled in the use of such instruments as we have been describing, and fully aware of their importance in adding to the security of ships, and shortening voyages, witnessed the contempt, or at least the neglect with which they were treated by those most interested in their general adoption. They saw vessels fitted up with every other description of costly equipments, with accommodations of the most showy description, and stores of all kinds in profusion, while neither a Sextant nor a solitary Chronometer ever formed, except accidentally, a part of their provision. If the captain *happened* to know any thing about such matters (for he was not required to do so), and knowing how advantageous they were to the success of his voyage, asked to be supplied with them, he was told "that he might provide himself with these instruments if he liked it;" and if the poor man could not afford to purchase them, the ship, however valuable, was actually allowed to sail away without the most important part of her nautical equipment. Can any absurdity, or, we might almost add, any crime, equal this? We could relate several instances, some of which have fallen under our own knowledge, and others we know to be well authenticated, of ships, and all their crews, passengers, and cargo, being lost, demonstrably so, merely from the want of a Chronometer, which, by costing the owners forty or fifty pounds, might have saved them as many thousands. Some owners are influenced by a petty spirit of economy, ill understood; but by far the greater number are misguided by their ignorance. Happy should we feel could we persuade the owners of ships, and those who insure them, to see that their best interest lies in providing the vessels, in the safety of which they are so deeply interested, with proper scientific instruments, and, as a necessary concomitant, securing the services of commanders really competent to use these instruments in a seamanlike manner. The importance of all such enlarged considerations has of late years been gradually making its way, to the great improvement of seamanship; for the owners of ships have begun to find out, less from any scientific knowledge of the matter, than from the mere instinct of gain, that an attention to this branch of a ship's outfit contributes to their pecuniary profit, and that if it is really worth while to provide Sextants and Chronometers, it is not less so to place them in hands trained to their use. Thus the standard of the characters of commanders of vessels is raised in proportion as their scientific acquirements are advanced, and, in the end, the whole community is benefited, by the increased security, expedition, and profits of commercial enterprise.

When enumerating the scientific instruments which have been introduced into the art of seamanship, we must not forget the Marine Barometer; an instrument, the principle of which, so long well known on shore, has only very lately been adapted to sea uses. This adaptation is accomplished in the simplest way imaginable, by merely contracting the throat of the tube which holds the mercury, at some convenient point of its length, in such a degree, that the oscillations of the fluid which the motions of the vessel would otherwise cause, are so much checked, that the height of the column can be observed, if not quite as accurately as on land, at least with sufficient precision to give the seaman indications of changes in the winds and weather.

We must repeat once more that it is not our purpose to write a complete treatise on seamanship, but merely to give a sketch of the most material advances which have been made since the Encyclopædia was first published, in this thoroughly practical science. It will be enough, therefore, to mention that the use of the barometer at sea consists in giving the seaman information, before hand, of the changes likely to take place in the direction as well as force of the wind; or, which is often fully as useful, to let him know that, in spite of appearances to the contrary, there will be no change. Cases intelligible to unprofessional persons may easily be furnished by any seaman's memory. We remember once, rounding the Cape of Good Hope, on a voyage from China, in a crazy bark, short-handed and ill-found, but with a fair wind, and the weather so moderate that every sail could be carried with advantage. To all appearance, squally, and perhaps stormy, weather was coming on; so that, had we not possessed a barometer, ordinary nautical prudence would have induced us to shorten sail before night, and thus we should have lost the charming fair wind which was co-operating with the current to sweep us rapidly across the bank of Lagulhas. But as the mercury indicated a continuance of fine weather, we carried on, sent the people to bed, rounded the Cape in safety, and reached the trade winds in time to accomplish a successful voyage to St. Helena and home. Nearly in the same region, and under circumstances very similar, we were once grievously tempted to trust rather to appearances than to the more substantial assurances of the barometer, and on the approach of night to make more sail instead of taking it in. As the darkness began, however, the confidence and pride of personal experience gave way to the warnings of the instrument. The sails were reefed, and every thing made snug for a breeze, greatly to the surprise of the sailors, who saw no cause for these precautions. Towards midnight a gale came on, which, had it not been anticipated, would speedily have taken in our sails for us, by blowing them from the yards; and the success of the voyage in this case also was chiefly due to the barometer.

Without dwelling further on this tempting branch of the subject of seamanship, we may venture to give one practical recommendation, which may possibly prove useful both to the owners and commanders of ships. It is, that as much responsibility as possible should always be made to rest on those instrumental parts of the equipment which science, and an adequate experience of its application, show to be really useful. Thus, we would have the owner of a ship, free, and even generous, in his supply of sextants, chronometers, barometers, and charts, to his captain, sure that, if he be chosen for his capacity, the paltry cost of such supply will, in the end, be repaid fifty fold. On the other hand, a commander so confided in, should study to use such means of instruction, as not abusing them. The captain should be possessed of a certain knowledge of their principles, in order to have that degree of faith in their application to practice, without which they may well prove worse than none at all. We have known some ships totally lost, and many voyages doubled in duration, merely by the ignorant misapplication of a figure, or of an algebraic sign. But if the captain knows the proper use of his instruments, he should trust to them, as he is himself trusted by his employers; and by resting upon them that responsibility which they are far more able to bear than he can be, however extensive his experience, he will make out his voyage in safety, and learn, by degrees, not only to feel, but to act on the belief of the uniformity of the laws of nature, in the midst of the wildest apparent confusion.

We had almost forgotten to mention, amongst the modern improvements in seamanship, the immense advantage of correct charts. To any one accustomed to use such charts as are now on board even the worst found ships, the sight of an old "sea map" is enough to make his hair stand on end. In the first place, on looking at the dangers which really exist, but which are omitted in the old charts, he wonders how ships in those times ever escaped destruction; and in the next, he finds the sea so thickly covered with rocks, and shoals, and those vague "vigias," now known to have no existence, that his admiration is great of the boldness of those mariners who could sail on at all during the night.

The government of most civilized countries having taken up this matter in earnest, and sent their surveyors abroad, like geographical missionaries, the world has been put in possession of charts of all those harbours, coasts, and seas which are most frequented, and so accurate is the construction of their maps, that ships duly provided with nautical instruments need scarcely ever incur the danger of running ashore, except by stress of weather, or experience any difficulty in finding safe passages amongst the most complicated sand banks, coral reefs, or any other description of submarine dangers, the terror and bane of old navigation.

It would lead us beyond our limits were we to go into further detail, in order to point out the various minor improvements which have been introduced into the practice of navigation; though we feel strongly tempted to describe the scientific remedies, for example, which have been applied to the steering compass by Professor Barlow, to correct the local attraction caused by the great additional quantity of iron that has lately been put on board all ships. For a similar reason, want of room, we must omit all mention of the improved methods of constructing ships, stowing their holds, making their masts, and, generally, the improved mode of rigging, fitting out, and working ships. These details being all parts of the same course of improvement, would enter naturally into an express treatise on seamanship, but are much too voluminous for this place.

There are two topics, however, on which we must be allowed to touch for a moment, before bringing this Appendix to a close. One is, the improved discipline of the British navy, and the consequent amelioration in the character of all the seamen of the country. The other is, the change in the armament of the ships of war, and the improvement in the training of our seamen to the duties required by this change. Both of these points have so material an influence on the prosperity of the country, and have become so completely part and parcel of the seamanship upon which its glory as a nation depends, that on this occasion we cannot pass them over in silence.

There can be no good seamanship without discipline, for it is as essential to the correct working of a ship that there should be a well-understood subordination established on board, as it is to the correct going of a clock that all its wheels and pinions should be made to fit, and be so placed as to work properly into one another. To carry on this illustration, it may be said, that whilst the mainspring of naval discipline is a sense of duty, even this strong motive would not be enough to produce the desired results, without the intermediate agency of an organised system of discipline, the object of which is, to assign to each person on board a specific set of duties, all which shall contribute to the main purpose; and, thus, as far as may be possible, to arrange and condense the energies of the whole into one course of uniform action, subject to the will of a supreme directing authority, who is responsible to the country at large.

In strictness, this well defined system of discipline belongs only to the naval department of seamanship, but in a great measure it also applies, by transmission, to the merchant service, where it works by the joint agency of custom, example, and the several interests of the parties concerned. So large a mass of the seamen of the country are employed in the navy, and so many naval officers are employed in the merchant service in peace; and as seamen, by the very nature of their lives, are perpetually changing from one service to another, a kind of amalgamation insensibly takes place, and thus the discipline established on board our ships of war, under the sanction of official authority and long established usage, pervades, more or less, the whole profession of the sea. In this view of the matter, the improved discipline of the navy has an important bearing on the well-being of the country, in all those relations connected with our insular situation; just as it might, by no strained analogy, be said, that the education, discipline, and fixed doctrines of the Established Church, have a salutary influence on the religious interests of the country, into whatever number of sects the population may be nominally divided.

The details of this branch of our subject might, we think, easily be made very interesting, but neither our space, nor the purpose of this Appendix, will admit of its being done here. We must content ourselves then, with saying that of late years great pains have been taken to raise the moral character of seamen by education, and by teaching them the advantages of sober and orderly habits, to beget a feeling of self-respect, which is at the root of all good discipline. Religious instruction, gently applied, and without any of that high-pressure cant, of which the sailor, of all mortals, has most abhorrence, has been most beneficially introduced. Light general reading has become general afloat, as well as elementary instruction; and there cannot be a doubt that the seamen are in consequence more correct in their moral conduct. The whole system of punishments, too, has been much modified; for in place of the lash which, at one time, regulated everything, a desire to prevent crime, and to lead the sailors to act from principle, have been substituted with great effect. In fact, when such a spirit as we have just alluded to, however engendered, pervades the captain, officers, and petty officers, the sailors, forming the mass of the crew, readily fall into the same current of duty, and all goes on cheerfully. The power of using corporal punishment exists still, and that it ever must exist in the navy, is the opinion of every person well-informed on the subject, and who knows the character of seamen and the duties which are required of them on board a man-of-war. There are no persons more fully convinced of this necessity than the sailors themselves, or who are more sensible that, under the wise and benevolent modifications now officially established in the navy, it is by far the most effective, and at the same time the most gentle, method of preserving order amongst those refractory subjects who unfortunately are to be found in every ship. Without the power of occasional corporal punishment, we conscientiously believe, it would be quite impossible to restrain such persons within any bounds of decency, or to prevent them from becoming a curse to those about them, whilst their lawless habits would unsettle the arrangements of the best regulated ship in the fleet, and, in the end, render her, instead of a bulwark to defend the country, a source of national weakness and dishonour.

Since the peace of 1815, all the maritime nations of the world have been gradually increasing the size of their ships of war, and adding to their weight of metal. Recently, too, the use of shells has been introduced afloat; a measure of questionable policy on the part of that nation which commenced it, but which we, and others, are of course obliged to adopt. The shells are not, as heretofore, fired from mortars only, but are thrown from the long guns used in ordinary warfare in projecting solid shot. How far this new weapon may modify the seamanship of naval engagements we are not prepared to say. In the mean time, great pains have been taken to train a large body of seamen gunners, including of course a proportion of highly-educated officers of all ranks; whilst guns of the most approved calibre for shell practice, have been placed on board every ship in the navy. The establishment of this new system of exercise, through the agency of an express gunnery department of instruction, and the manner in which it has been enforced in all our ships, have produced a marked effect on the habits and character of the seamen throughout the fleet.

Before closing it may be expected that we should say something of the probable influence of steam navigation on naval warfare; and we do not shrink from committing ourselves by an opinion on this point, though it be one much disputed amongst professional men. Our notion is, that the introduction of steam will make no difference whatever in the result of any contest in which we shall be engaged, however the means may be modified thereby. The battle must still be fought, as it always has been, and ever must be fought, by large bodies of disciplined men, properly led, and properly armed; and the victory, as formerly, will be decided in favour of those who have the best national spirit to urge them on, or who, being equal in this respect, bring the greatest number into the field. Line-of-battle ships, in this view of the subject, are merely convenient vehicles in which warriors are brought, hand to hand, to settle their differences by hard fighting. Steam will enable them either to come together more quickly, or to avoid coming together at all, as the case may be; but neither steam, nor any other mechanical agency, will ever dispense with the moral agency of trained men, by whose conduct and courage alone the issue of all wars must be determined. We have heard it suggested, and we think with not less probability than ingenuity, that steamers in war will take the same place in fleets that cavalry have long done in armies. It is a very important place, no doubt, but it is not one which decides the eventual fate of the war; *that* is always the work of the infantry. The cavalry protect the flanks, and otherwise help the infantry to get into action with that of the enemy opposed to them, and when these are broken, they cut in upon them and do much execution. In like manner, armed steamers will guard the edges of fleets, tow three-deckers into action, and, when the enemy is discomfitted, will come in with desperate effect to reap the iron harvest. Still we contend, that the great battle which decides the fate of empires, must ever be fought by men, that is, by numerous bodies of disciplined men acting together, duly led, and fighting under the influence of national sentiment. It is impossible to impart this sentiment to machinery; and though we do not deny that, occasionally, a steamer, armed with guns of enormous calibre, may grievously annoy a line-of-battle ship in a calm, or under some other untoward circumstances, we are fully satisfied that by proper arrangements, every sailing ship may be so armed and worked, that the moral and physical agents on board of her will prove an overmatch for that power which relies, for its superiority, on its mechanical machinery alone. We have no doubt, too, that ere long steam engines will find a place on board all large ships of war (high-pressure engines of course); for the absurd and totally unsubstantial prejudice against this modification of steam power will, in the event of a war, if not long before, give way to the prodigious convenience in the way of stowage, and other advantages, which point out the expediency of its use in all sea-going vessels without exception. To what extent ships of war may require to be fitted with steam power, is a question which must depend on circumstances that cannot be foreseen; but that, eventually, they must have, within themselves, some such means of locomotion, besides what they may borrow from tug boats, we hold to be quite certain. (B T.)

SEARCH-Warrant, in *Law*, a kind of general warrant issued by justices of peace or by magistrates of towns, for searching all suspected places for stolen goods. In Scotland this was often done formerly; and in some English law-books there are precedents requiring the constable to search all such suspected places as he and the party complaining shall think convenient; but such practice is condemned by Lord Hale, Mr Hawkins, and the best authorities both among the English and the Scotch lawyers. However, in case of a complaint, and oath made of goods stolen, and that the party suspects that those goods are in a particular house, and shows the cause of such suspicion, the justice may grant a warrant to search not only that house, but other suspected places, and to attach the goods, and the party in whose custody they are found, and bring them before him or some other justice, to give an account how he came by them, and to abide such order as to law shall appertain. This warrant should be directed to the constable or other public officer, who may enter a suspected house and make search.

SEATON, a town in the hundred of Colyton, in the county of Devon, 150 miles from London. It consists chiefly of one street, and stands on the sea-shore, in a very pleasant but secluded situation. It is much resorted to as a sea-bathing place during the summer months; and there is a considerable fishery carried on from hence. It has a parish church and an Independent chapel. The population amounted in 1821 to 1745, and in 1831 to 1803, taken at a period of the year when there is no occasional residence.

Seaton-Carew, a township in the parish of Stranton, in the county of Durham, in the ward of Stockton, two miles from Hartlepool, seven from Stockton, and 256 from London. It stands close to the sea-shore, near the influx of the river Tees into the sea. It is well adapted for sea-bathing, which has caused an increase in the number of the houses. The chief occupation of the inhabitants is that of fishing. Their number amounted in 1821 to 704, and in 1831 to 736; but it has much increased in the last seven years.

SEBACIC Acid, so called because it is procured from fat.

SEBASTIANO, called *Del Piombo*, from an office in the lead-mines given him by Pope Clement VII., was an eminent Venetian painter, born in the year 1485. He was first a disciple of old Giovanni Bellino; continued his studies under Giorgione; and having attained an excellent manner of colouring, went to Rome, where he insinuated himself into the favour of Michel Angelo. He has the reputation of being the first who invented the art of preparing plaster-walls for oil-painting; but he was so slow and lazy in his work, that other hands were often employed to finish what he had begun. He died in 1547.

SEBASTIAN, St, a considerable and strongly fortified city of Spain, the capital of the province of Guipuscoa. It is built on a tongue of land projecting into the sea. The north point of the mountain Orgullo, being the high land of St Sebastian, is about three miles to the west of Port Passage, on which is built the castle of Mota, which serves as a guide on one side, as the light-house does on the other entrance to the bay, which is a very narrow strait, not admitting through it more than two vessels at a time; but the bay, when entered, is secure for vessels furnished with good ground-tackle, which sunken rocks make very necessary.

For the protection of vessels trading with the town, there are piers, within which ships of 300 tons may enter at low water; but when the tide is out they lie dry on a hard bottom.

The city is defended by strong works on the land side, and has only two gates. St Sebastian is better built than most Spanish towns, the streets being wide, straight, and well paved. The houses, also, are large and well built. The town contains, besides warehouses, about 700 houses, three parish churches, five monasteries, a hospital, and about 12,000 or 13,000 inhabitants. The plaza, or square, is a very fine object.

This place was the seat of the Guipuscoa Society, one of the largest trading associations in Spain, which formed a junction with the Manilla Company; and these had almost a monopoly of the trade with Caraccas in the western colonies of Spain, and with the Philippine Islands in the East Indies. It was then a port of vast commercial importance, having, besides those branches, a considerable share of the export trade of wool. At that period there were large establishments for making ropes and cables, many anchor-smiths and nail-smiths, and such other occupations as are connected with the equipment of ships; but political circumstances have changed and much diminished the commerce of this place.

The important position of this place has drawn upon it much of the calamity of war. In former times it had been frequently besieged and occupied by opposing parties. It was treacherously seized by the French in 1808, and was occupied by them till 1813. When the battle of Vittoria had been gained by the Duke of Wellington on the 21st of June, a way was opened for the British army to attack this city, into which the French had thrown a powerful garrison, who defended it with great bravery and skill. The British army invested the place, and attempted to storm it on the 25th July; but having been repulsed, they besieged it in regular form, and with the loss of many lives it was stormed and carried on the 31st of August. During the assault the town was set on fire and nearly destroyed; and a scene of misery was exhibited to the unfortunate people, in the rage of the storming soldiery, as well as in the progress of the flames, which will long be recollected with horror by the wretched sufferers. The city was, however, speedily rebuilt, and commerce gradually returned. The civil war in some measure centred here, it being the chief point by which the queen's party received their supply of warlike stores from England. Its trade has, however, received a most disastrous check. The castle of Mota is in lat. 43. 19. N., and long. 1. 59. W.

SEBESE, or Pulo Bicie, a small island in the Straits of Sunda. Long. 105. 27. E. Lat. 5. 50. S.

SEBSVAR, a town of Khorassan, in Persia, 180 miles north-west of Herat. It was taken in 1381 by Timur, who made a cruel example of the inhabitants who revolted from his yoke, burying alive ten thousand of their number.

SEBURAI, Seburæi, a name which the Jews give to such of their rabbin or doctors as lived and taught some time after the finishing of the Talmud.

SECALE, Rye. See Agriculture.

SECANT, in *Geometry*, a line that cuts another, or divides it into parts.

SECANT, in *Trigonometry*, denotes a right line drawn from the centre of a circle, which, cutting the circumference, proceeds till it meets with a tangent to the same circle.

SECEDERS, a numerous body of Presbyterians, who have withdrawn from the communion of the Established Church in Scotland.

In order that the causes from which the Secession originated may be clearly understood, we shall introduce an account of that important event by a brief sketch of the previous history of the Scottish church.

James I. after his accession to the English throne, entertained an ardent desire to form the Church of Scotland as much as possible upon the model of that in England; and his son Charles, with the assistance of Archbishop Laud, endeavoured to carry the design into execution, by establishing canons for ecclesiastical discipline, and introducing a liturgy into the public service of the church. Great numbers of the clergy and laity of all ranks took the alarm at what they justly considered as a bold and dangerous innovation; and after frequent applications to the throne, they at last obtained the royal proclamation for a free parliament and General Assembly. The Assembly met in 1638, and began their labours with a repeal of all the acts of the six preceding parliaments, which had favoured the introduction of Episcopacy. They condemned the liturgy, together with every branch of the hierarchy. They cited all the Scottish bishops to their bar, and after having excommunicated nine of them, and deposed five from their episcopal office, they restored kirk-sessions, presbyteries, and synods, provincial as well as national. These proceedings were ratified by the parliament which met in 1640. The law of patronage, however, was in full force for several years after this period; but great care was taken that no minister should be obtruded on the people contrary to their inclination; and in 1649 patronage was abolished altogether, as an oppressive grievance.

The restoration of Charles II. in 1660, produced a total change in the state of ecclesiastical affairs in Scotland. All that the General Assembly had done from 1638 to 1650 was rendered null and void; the covenants were pronounced to be unlawful, Episcopacy was restored, and the king was declared to be the supreme head of the church in all matters civil and ecclesiastical. During this period, under the sway of Lauderdale and his associates, the Presbyterians were not only subjected to fines, imprisonment, and exile, but numbers of them were publicly executed, for their adherence to their political and religious principles.

At the memorable era of the Revolution, the affairs of the church underwent a complete change. The first parliament which met after that event abolished prelacy and the king's supremacy in ecclesiastical affairs. They ratified the Westminster Confession of Faith, together with the Presbyterian form of church government and discipline, "as agreeable to the word of God, and most conducive to the advancement of true piety and godliness, and the establishment of peace and tranquillity within these realms." That same parliament abolished patronage, and vested the election of ministers in the heritors and elders, with the consent of the congregation.

At the first General Assembly held after the Revolution, a most conciliatory spirit was manifested, and a wide door of admission into the national church was opened to the episcopal ministers, on the most lenient terms. Great multitudes of the conforming clergy were thus induced, for the sake of the benefice, to transfer their respect and obedience from the bishop to the presbytery, and were received into ministerial communion on merely acknowledging "that the church government, as now settled by law, is the only government of this church." The admission of these time-servers into the church laid the foundation of those measures which ultimately led to the secession.[1]

In the reign of Queen Anne, the true Protestant religion was ratified and established, together with the Presbyterian form of church government and discipline; and the unalterable continuance of both was declared to be an essential condition of the union of the two kingdoms in all time coming. In 1712, the law respecting patronage was revived, in resentment, it has been said, of that warm attachment which the Church of Scotland discovered to the family of Hanover; and about the same period the imposition by the government, of the oath of abjuration, was a fertile source of discord and strife, both among ministers and people. This oath was regarded with great jealousy, and was peculiarly obnoxious to the Presbyterian clergy, both because its avowed design was the security of the Church of England, and because it seemed to imply an approbation of diocesan Episcopacy, with the ceremonies of that church, and a recognition of the queen's supremacy in matters of religion. About a third part of the clergy, including the founders of the Secession Church, positively refused to swear this offensive oath; though they were enjoined to do so on pain of ejection from their churches, and of paying an exorbitant fine. A train of events which followed in rapid succession soon made it manifest that the dominant party in the Scottish church were, if not hostile, at least indifferent, to the most important doctrines of religion, and ready to sacrifice the liberties of the people at the shrine of civil authority. This charge was proved beyond the possibility of contradiction, by their conduct towards the presbytery of Auchterarder in the year 1717, with regard to what has since been denominated the Auchterarder Creed, by their vindictive proceedings against the twelve minsters known by the name of "Marrow Men," who endeavoured to check the progress of error by the diffusion of sound doctrine, along with their condemnation of the doctrines of the book entitled the Marrow of Modern Divinity, in the years 1720–21, and especially by the leniency of their dealings with Professor Simpson of Glasgow, who, though found guilty of teaching a system of deism rather than Christian theology, in his prelections to the students of divinity, received no higher censure than simple suspension.

For some time after the revival of patronage in 1712, the severity of the law was greatly mitigated by the general disinclination, on the part both of ministers and patrons, to avail themselves of its provisions in opposition to the feelings of the people; but this state of things was speedily changed. After the lapse of a few years, patrons no longer hesitated to avail themselves of their legal rights, and ministers were no longer disinclined to accept of presentations when given contrary to the wishes of the congregation. But on the part of the people acts of resistance became more frequent and more obstinate, though they were almost uniformly unsuccessful; for the ruling party among the clergy were firm in their resolution that the law of patronage should be carried into effect. They found themselves, however, placed in circumstances of peculiar difficulty; for not only were the people loud in their remonstrances against violent settlements, but a considerable party of the ministers themselves espoused the popular side, and not only strenuously opposed the intrusion of ministers upon congregations, but obstinately refused to carry into effect the decisions of the Assembly. To obviate this difficulty, in 1729 they appointed a committee of their own number to meet and ordain the obnoxious presentee; and for a period of twenty years this expedient was resorted to in cases where the presbytery proved refractory. The excitement of the people, and their resistance to the yoke of patronage, continued to increase; violent settlements prevailed in every part of the country; and in some cases the popular feeling was so strong, that it was deemed necessary to employ an armed force to carry into effect the decisions of the church-courts. At the meeting of the Assembly in 1730, there were no fewer than twelve cases of appeals on the part of congregations against the intrusion of obnoxious ministers; but the dominant party were so determined to crush all opposition to their enactments, that they not only dismissed these appeals, but solemnly enacted, at this meeting of the Assembly, that henceforward no reasons of dissent "against the determination of church judicatures" should be entered on the record. The Assembly of 1731 followed closely in the footsteps of its predecessor. By the law of patronage it was provided, that if the patron suffered six months to elapse without exercising his right of presentation, the presbytery to which the vacant parish belonged was empowered to take steps for its settlement. The presbyteries in these cases frequently gave the people the right of choosing their ministers; and with the view of destroying this last remnant of popular election, an overture was laid before the Assembly of 1731, proposing, that when the right of appointment devolved upon presbyteries, the power of election in vacant parishes should belong only to the elders and Protestant heritors, and, in royal burghs, to the elders, magistrates, and town-council. This overture was transmitted to the different presbyteries, that, according to the regulations of the barrier act, their opinion respecting it might be given at next meeting of the Assembly; and though a great majority of those presbyteries from whom reports were received, expressed disapprobation of the measure, the supporters of the overture obtained a majority of the Assembly of 1732 in its favour.[1]

---

[1] For a description of their character, see Burnet, vol. i. p. 158, folio edition.

Among the opponents of the measures of the Assembly in 1732, Mr Ebenezer Erskine, minister at Stirling, held a prominent place. His talents and learning, his faithfulness in the discharge of his ministerial duties, and his intrepidity and zeal in the popular cause, had secured to him the respect and esteem of his brethren, as well as extensive influence among the people. In the various important questions which had been agitated after his entrance into the ministry, the abjuration oath, the controversy respecting the Marrow of Divinity, and the process carried on against Professor Simpson, he had shown himself an active and fearless opponent of the measures pursued by the ruling party in the church. He was not only one of those who signed the representation of grievances laid before the Assembly in 1732, but being a member of Assembly that year, he spoke and protested against its rejection. Being at that time moderator of the synod of Perth and Stirling, he opened the meeting at Perth, on the 10th of October following, with a sermon from Psalm cxviii. 22, in the course of which he remonstrated against the act of the preceding Assembly with regard to the settlement of ministers, alleging that it was contrary to the word of God and the established constitution of the church. These statements gave great offence to several members of synod, and after the court was constituted, and a new moderator chosen, a formal complaint was lodged against him, for uttering several offensive expressions in his sermon.[2] Many of the members declared that they heard him utter nothing but sound and seasonable doctrine; but his accusers insisting on their complaint, obtained the appointment of a committee of synod, to collect what were called the offensive expressions, and to lay them before the next diet in writing. This was done accordingly, and Mr Erskine having been heard in reply to the charges made against him, a keen debate of three days ensued, and at last the synod, by a majority of six votes, found Mr Erskine censurable for some expressions in his sermon, "tending to disquiet the peace of the church, and impugning several acts of Assembly, and proceedings of church judicatories." Against this sentence Mr Erskine protested and appealed to the General Assembly. But in spite of his protest and appeal, the synod proceeded in the cause, and agreed to "rebuke Mr Erskine, and admonish him to behave orderly for the future;" and they at the same time appointed the "presbytery of Stirling to inquire anent his after behaviour at their privy censures, and report to the next synod." Mr Erskine not appearing when called upon, the synod resolved that he should be rebuked at their next meeting in April. All attempts at accommodation proving fruitless, the Assembly which met in May 1733 affirmed the sentence of the synod, and appointed Mr Erskine to be rebuked and admonished at the bar of the Assembly. Mr Erskine, however, declared that he could not submit in silence to the rebuke and admonition, and presented a written protest, to the effect, that as the Assembly had found him censurable, and had rebuked him for doing what he conceived to be agreeable to the word of God and the standards of the church, he should be at liberty to teach the same truths, and to testify against the same or similar evils, on every proper occasion. To this protest Messrs William Wilson, minister at Perth, Alexander Moncrieff, minister at Abernethy, and James Fisher, minister at Kinclaven, gave in a written adherence, under the form of instrument. The Assembly having refused to permit the protest to be read, the four protesters left the paper on the table and withdrew, intending to return to their respective charges, and act agreeably to their protest, as circumstances might require. Here the matter would in all probability have terminated, as at this period none of the four entertained any intention of a formal separation from the national church. But an overruling Providence had ordered it otherwise. The court had proceeded to a different business, when the protest, which had fallen from the table, was accidentally picked up by a minister, who, perusing the contents of it, rose with great indignation, and called the attention of the Assembly to the insult which had been offered to their authority.[3] The protest being read, a great uproar ensued, and the Assembly ordered their officer to summon the four brethren to appear at the bar of the court next day. They obeyed the citation, and a committee was appointed to retire with them in order to persuade them to withdraw their paper. The committee having reported that their persuasions had produced no effect on the minds of the brethren, the Assembly ordered them to appear before the Commission in August following, and retract their protest; and if they should not comply, and testify their sorrow for their conduct, the Commission was empowered to suspend them from the exercise of their ministry, and in case of their acting contrary to the sentence of suspension, the Commission should proceed to a higher censure.

The Commission met in August accordingly, and the four ministers still adhering to their protest, were suspended from the exercise of their office. At the meeting in November, addresses were received from a number of presbyteries and synods, recommending lenity and forbearance towards the suspended ministers, and many members of the Commission strenuously supported the same view. The question, however, was put, "Proceed immediately to inflict a higher censure," or "Delay the same till March;" and the votes being equal on both sides, Mr John Gowdie, the moderator, one of the ministers of Edinburgh, gave his casting vote to proceed to a higher censure. At this stage of the proceedings the Commission proposed certain terms of accommodation, which the suspended ministers, after mature deliberation, declared they could not conscientiously accept. The Commission, therefore, on the 16th of November 1733, passed sentence upon them; loosing their relation to their respective charges, declaring their churches vacant, and prohibiting all ministers of the Church of Scotland from employing them in any ministerial function.

---

[1] Reports were received from forty-nine presbyteries; six approved of the overture without alteration, twelve on condition that certain important amendments were introduced, while thirty-one gave it their unqualified condemnation. Eighteen presbyteries gave in no report.

[2] The persons who took the lead in moving for investigation were, Messrs Adam Ferguson, minister at Logierait; James Mercer, minister at Aberdalgie; James Mackie, minister at Forteviot, afterwards at St Ninians; and the Laird of Glendoig, ruling elder.

[3] It is stated by Mr Adam Gibb, that the person who picked up Mr Erskine's protest was Mr James Nasmith, minister at Dalmeny.

The sentence being intimated to them, they protested that their ministerial office and relation to their respective charges should be held as valid as if no such sentence had passed; that they were now obliged to make a *secession* from the prevailing party in the ecclesiastical courts; and that it should be lawful for them to preach the gospel, and discharge all the duties of the pastoral office, according to the word of God, and the principles and constitution of the Church of Scotland.

The Secession properly commenced at this date. Accordingly the ejected ministers declared in their protest, that they were laid under the disagreeable necessity of seceding, not from the principles and constitution of the Church of Scotland, to which they expressed their steadfast adherence, but from the present church-courts, which had thrown them out from ministerial communion. In the new and trying circumstances in which they were placed, they conducted themselves with great caution and prudence. A few weeks after their expulsion from the national church, they met, according to previous appointment, at Gairney Bridge, a small village in the neighbourhood of Kinross, on the 5th of December 1733. Having spent the whole of that and the greater part of the succeeding day in prayer and pious conference, they finally resolved to constitute themselves into a presbytery, under the designation of *the Associate Presbytery*. This presbytery, at its first formation, consisted only of the four ejected ministers; for though Messrs Ralph Erskine and Thomas Mair were present at this interesting meeting, they were merely spectators. Anxious, however, to avoid every thing like rashness or precipitancy, and cherishing a solemn impression of the responsibility attached to their conduct, in the remarkable circumstances in which they were placed, the seceding ministers resolved to hold their meetings chiefly for prayer and religious conference, and to defer proceeding to any judicial acts till they should see whether the ecclesiastical courts would retrace their steps. They considered it necessary, however, to publish a Testimony to the doctrine, worship, and government of the Church of Scotland, and a statement of the grounds of their secession from the national church. This has been since known by the name of the Extrajudicial Testimony.

In the Assembly which met in May 1734, a conciliatory spirit was manifested by the ruling party; the agitated state of popular feeling, and the knowledge that the Seceders had many friends among the clergy themselves, disposed them to make some concessions to prevent the spread of disaffection. When the commission-book was examined, there were some reservations made in the approval of its proceedings; the act of 1730, forbidding church-courts to record dissents and protests, and the act of 1732, respecting the settlement of vacant parishes, were repealed; the Commission was appointed to petition his majesty and the parliament for the repeal of the patronage act; and they authorized the Synod of Perth and Stirling to receive the ejected ministers into the communion of the church, and restore them to their respective charges, but with this express direction, that the "synod should not take upon them to judge of the legality or formality of the former procedure of the church judicatories in relation to this affair, or either approve or censure the same." But as the appearances of reformation which had been exhibited were, in the opinion of the four seceding brethren, dictated merely by a calculating worldly policy, and by no real regard for the cause of truth, after solemn and repeated deliberation, they were unanimously of opinion that, in existing circumstances, it was their duty to remain in a state of separation, till they should see unequivocal and decided evidence that the cause of defection was in reality abandoned. Having prepared a statement of the reasons of their refusal, and the terms upon which they were willing to return to the Established Church, they published it some time before the meeting of Assembly 1735. The proceedings of the Assemblies of 1735 and 1736 seemed to the seceding ministers fully to justify the opinion which they had formed respecting the measures proposed in the preceding Assembly, and to dispel, for the time at least, all hopes of a re-union with the Established Church; and they now considered it "full time to proceed to the exercise of the powers with which they were intrusted by the Head of the church, for the vindication of His truths and ordinances, and for the relief of the Christian people, by supplying them with sermon."[1] They now prepared what they termed an Act, Declaration, and Testimony to the doctrine, worship, government, and discipline of the Church of Scotland, and condemning the numerous instances of defection from these, both in former and in the present times. Some time after this, having received the accession of Messrs Ralph Erskine of Dunfermline, Thomas Mair of Orwell, Thomas Nairn of Abbotshall, and James Thomson of Burntisland, the Associate Presbytery now consisted of eight members. Numerous applications for sermon having been received from all parts of the country,[2] and the seceding ministers having now renounced all hopes of a re-union with the church, resolved to adopt measures for extending and perpetuating the benefits of the Secession; and accordingly Mr Wilson of Perth, a person of great ability and learning, was chosen professor of divinity, and intrusted with the education of candidates for the ministry.[3] These measures necessarily produced a complete separation between them and the Established Church. The Assembly of 1739 declared the refractory ministers worthy of deposition; but, from motives of expediency, delayed giving sentence against them till next year, when they were all deposed, and ordered to be ejected from their churches. In some places, such as Stirling and Perth, the seceding ministers were forcibly excluded from their usual places of worship the first Sabbath after the decision of the Assembly, while in others, such as Dunfermline and Burntisland, they continued to occupy their pulpits for at least two years after sentence of deposition was pronounced against them. All of them, however, continued to discharge the duties of the ministry in their respective congregations, who still adhered to them, erected places of worship for them, and provided for their support. Meanwhile cases of violent settlements of ministers increased throughout the country, and the opposition was frequently so formidable, and popular excitement so great, as to render the attendance of a guard of soldiers necessary at ordinations. These contests had of course a powerful influence in increasing the adherents of the seceding ministers. New accessions were made to them from all quarters. Some even of the probationers of the Established Church placed themselves under their superintendence, and their theological hall was in such a flourishing condition that, in the year 1741, it was attended by a greater number of students than any of the Scottish universities except Edinburgh.[1]

---

[1] Testimony of the United Associate Synod, p. 52.

[2] During the years 1737–38, upwards of seventy petitions for sermon were laid on the table of the presbytery.

[3] Mr Wilson devoted the months of March, April, and May, to his course of theological tuition. He not only read his lectures, but conducted the whole business of the class, in the Latin language.

The numbers of the seceding ministers continuing rapidly to increase, a new arrangement was adopted on the 11th of October 1744, by which they were formed into three presbyteries, under one synod. The first meeting of the Associate Synod was held at Stirling on the first Tuesday of March 1745, at which period it had under its inspection about thirty settled congregations and sixteen vacancies in Scotland, besides several congregations in Ireland. The Seceders, in common with the great body of the religious Presbyterians in Scotland, both clergy and laity, entertained great veneration for the national covenants; and as the practice of public covenanting had, for a considerable period, been neglected in Scotland, they expected that the revival of it would have a powerful effect in advancing the work of reformation. An overture to this purpose had been deliberately prepared by a committee of presbytery, which, after various amendments and enlargements, was finally adopted by the presbytery at Stirling, on the 23d of December 1743. And on the 28th of the same month, which was observed as a day of solemn fasting and humiliation, the confession of sins was read, and the engagement to duties subscribed by fifteen ministers, in the presence of a numerous assembly. And when the presbytery met at Edinburgh, on the 14th of February 1744, they enacted that the renewing of the covenant should be the term of ministerial and Christian communion. An unhappy controversy now, however, arose respecting the religious clause of some burgess-oaths, which, it was alleged, was utterly inconsistent with the oath of the covenants and with the Secession Testimony.[2] One party insisted that no Seceder should be allowed to swear this oath, while the other urged the exercise of mutual forbearance. So sharp was the contention between them, that at the meeting of synod in April 1747, after several long and stormy discussions, an entire separation took place between the contending parties. Never, perhaps, was the truth of Father Paul's remark more strikingly verified, "In verbal contentions, the smallness of the difference often nourishes the obstinacy of the parties." Those who condemned the swearing of the burgess oath as sinful, and inconsistent with the Secession Testimony, were called "Antiburghers," and the other party, who contended that it should be declared not to be a term of communion, were designated "Burghers." The latter made various attempts to bring about a reconciliation with the opposing party, by proposing a meeting for prayer and friendly conference, but without success. And the "Antiburghers" not only refused to agree to the proposal, but, after several previous steps, went the length of passing sentence of deposition and excommunication, with all due formality, on Messrs Ebenezer and Ralph Erskine, James Fisher, and the other ministers who had adopted the opposite views respecting the swearing of the burgess oath. Each party claimed to itself the name and lawful constitution of the Associate Synod; but, for the sake of distinction, the Burghers were termed the Associate, and the Antiburghers the General Associate Synod. A furious controversy raged between them for a number of years, and, both from the pulpit and the press, the one party indulged in invectives against the other. In the course of time, however, this hostility subsided; a feeling of cordiality gradually gained ground; and, after a separation of nearly eighty years, the two bodies were again united into one.

These divisions among the Seceders afforded an excellent opportunity to the dominant party in the national church to have regained their lost influence with the people; but, instead of availing themselves of it to check the progress of the Secession, they only became more resolute in enforcing the law of patronage. The doctrine which they taught at this time in their pulpits, it has been said, "could neither be called Christian nor heathen, but was a compound of both;" and all petitions for the redress of grievances, and all resistance to their arbitrary decrees, were silenced by the strong arm of power. "The language of the majority in Assemblies at this time," says the late Sir Henry Moncrieff,[3] "universally was, that the secession from the church, instead of increasing, was on the decline, and that the superior character and talents of the established clergy were gradually weakening its resources, and would ultimately exhaust them. Experience has not verified these sanguine expectations. At the distance of a few years after Dr Robertson retired, the people, disgusted with unsuccessful processes before the Assembly, relinquished the plan of their predecessors, and came seldom to the Assembly with appeals from the sentences of the inferior courts appointing the settlement of presentees whom they resisted. But they began to do more quietly, or with less observation than formerly, what was not less unfriendly to the establishment. In ordinary cases, they now leave the church-courts to execute their sentences without opposition, and set themselves immediately to rear a meeting-house, which very frequently carries off a large portion of the inhabitants of the parish." This state of comparative quiescence was not, however, produced without long and severe struggles; and for many years the disputes in the church-courts respecting the settlements of ministers were incessant. In the year 1751, an unpopular minister having been presented to the church and parish of Inverkeithing, the presbytery of Dunfermline refused to proceed with his settlement, and the synod of Fife, who were next appointed to ordain him, proved equally refractory. The affair was brought before the Assembly of 1752, and they peremptorily enjoined the presbytery of Dunfermline to proceed with the ordination of the presentee, and ordered all the members of presbytery to attend on that occasion. Six ministers who absented themselves from conscientious scruples were brought to the bar of the Assembly. One of their number, Mr Thomas Gillespie, minister of Carnock, was immediately deposed, and three others were afterwards suspended. Mr Gillespie, notwithstanding this sentence, continued to discharge his ministerial duties, and a few years afterwards he and Mr Thomas Boston of Oxnam and Mr Collier formed themselves into a presbytery, and became the founders of that numerous and respectable body of dissenters entitled the Synod of Relief.

When such proceedings were systematically carried on in the courts of the Established Church, it is not to be wondered at that the spirit of disaffection should continue to spread among its members, and that the numbers of the Seceders rapidly increased, in spite of the strife that prevailed among themselves at this period. Not only did the Associate Synods steadily extend their influence in Scotland by the accessions which they were constantly making to the number of their adherents, but they sent preachers to England, to Ireland, and even to America, and erected a considerable number of Secession congregations in these countries. The controversy respecting the burgess-oath gradually exhausted itself; but towards the close of the eighteenth century, both synods were disturbed by an angry discussion respecting the power of the magistrate in matters of religion, and the obligation of the national covenant upon posterity. In 1796 the synod commenced their revision of the Testimony, a business of no small importance and difficulty, as this document "consisted of two hundred octavo pages, and included all the controversial points in divinity and church-government which had been discussed in this country for successive generations." During the progress of this laborious work, which lasted for a period of nearly eight years, considerable dissatisfaction was expressed by a small minority; and when at length the revision was brought to a close in May 1804, and the Introduction, Narrative, and Testimony, as corrected and enlarged, were adopted by the synod as the term of admission for those who shall apply for joining in communion with them, five ministers, Messrs Whytock, Aitken, Chalmers, Hog, and M'Crie, protested against the decision, and, after various ineffectual attempts at accommodation, left the body, and formed themselves into a distinct presbytery.

---

[1] Letter from Mr R. Erskine to Mr Whitefield, dated the 10th of April 1741.

[2] The following is the clause referred to: "I protest before God and your Lordships, that I profess and allow with my heart the true religion presently professed within this realm, and authorized by the laws thereof; and I shall abide thereat, and defend the same, to my life's end, renouncing the Roman religion called papistry."

[3] Appendix to Life of Dr Erskine, by Sir H. Moncrieff Wellwood, Bart., p. 464.

Nearly about this period a fierce controversy was carried on in the Associate or Burgher Synod respecting the same subject, which was under consideration for a considerable time, and various controversial publications issued from the press respecting it. At length, in April 1797, the synod by a majority agreed to the following motion. "That whereas some parts of the standard books of this synod have been interpreted as favouring compulsory measures in religion, the synod hereby declare that they do not require an approbation of any such principle from any candidate for license or ordination; and whereas a controversy has arisen among us respecting the nature and kind of the obligation of our solemn covenants on posterity, whether it be entirely of the same kind upon us as upon our ancestors who swore them, the synod hereby declare, that while they hold the obligation of our covenants upon posterity, they do not interfere with that controversy which has arisen respecting it, and recommend it to all their members to suppress that controversy, as tending to gender strife, rather than godly edifying." Notwithstanding this decision, the ferment which had been excited by the discussion on this subject rather increased than abated, and the question was again brought under the notice of the synod in September 1799. After a lengthened discussion, it was decided by a large majority, that "the synod adjourn the further discussion of this question till a future meeting, and in the mean time appoint a committee to draw up a synodical address to the people of their charge, expressive of their adherence to the doctrine, worship, discipline, and government of the Church of Scotland." Against this decision several members protested, and two of them, Messrs Willis and Hyslop, declared in their protest, that as the synod had refused to reverse their former act, they would no longer acknowledge their authority. In consequence of this declaration their names were erased from the roll, and shortly afterwards they, along with Mr Watson, minister of Kilpatrick, constituted themselves into a distinct presbytery, and became the founders of that body which is ordinarily known by the appellation of the Original Burgher Synod. An attempt was made by these separatists to obtain possession of the property belonging to the synod, by alleging that they had abandoned the principles which their predecessors in the Secession had always maintained. An appeal to the courts of law was made on this point, in the case of the Associate congregation in Perth. Mr Jervie, one of the ministers of this congregation, joined the Original Burgher Synod, while his colleague Mr Aikman continued in connection with the Associate Synod. The congregation were also divided in sentiment, and each party claimed the exclusive possession of the manse and place of worship. After a long and expensive litigation, in the course of which the process was carried from the inferior courts to the House of Lords, and thence remitted back to the Court of Session, it was ultimately decided that the defenders had not departed from the original standards and principles of the association, and that the pursuers had separated from the congregation to which they belonged, without any assignable cause, and without any fault on the part of the Associate Synod. They had, therefore, no right to disturb the defenders in the possession of their property. The question was one of great importance, and the principle laid down in this instance as the ground of judgment, has been since regarded as the settled law of the country in all similar cases.

No other event of much importance occurred in the history of the Secession Church, till the period when the two great branches of which it was composed were again happily united into one. A junction had previously taken place between the Burgher and Antiburgher ministers in America, Nova Scotia, and Ireland. For a number of years an amicable feeling had gradually gained ground among the ministers and people connected with both branches of the Secession, and their intercourse in bible, missionary, and other religious societies tended powerfully to strengthen the feeling of mutual regard. From the moment that the proposal of a junction was made, both synods entered on the matter with cordiality and zeal. The religious public generally took considerable interest in the movement. The town councils of Glasgow and Paisley abolished the religious clause of the oath which had occasioned the strife, and the Convention of Royal Burghs unanimously recommended its entire abolition, for the express purpose of removing any obstacles that might obstruct the progress of this desirable event. At length the articles of union having been agreed upon and sanctioned by both synods, and all the necessary preliminaries settled, the union was completed on the 8th of September 1820, in Bristo Street church, Edinburgh, the spot where, seventy-three years before, the separation had taken place.

All the ministers of the Associate Synod became members of the United Synod; but Professor Paxton, and other nine ministers of the General Associate or Antiburgher Synod, refused to concur in the union, and soon after formed a junction with Professor Bruce, Dr M'Crie, and other members of the Constitutional Associate Presbytery, who withdrew from the Antiburgher body in 1806.

Since the period of the union the Secession Church has continued rapidly to increase in numbers and strength, and the extraordinary controversy which is at present agitating the whole country has brought the Seceders much more prominently into view than during any preceding era of their church. The question respecting the power of the magistrate in religious affairs had frequently been discussed among Seceders themselves, but of late years it has become a matter of national interest. The founders of the Secession Church doubtless approved of the interference of the civil magistrate in matters of religion; but they appear to have changed their opinions on this subject at no distant period after their secession from the Established Church, as appears from the language of the Associate presbytery as early as 1743, in their answers to Mr Nairn: "If true religion became a part of the civil constitution, it inevitably follows that the church became a part of the state, which doctrine, as it is absurd in itself, lays a plain foundation for Erastianism, overturning the distinction betwixt the kingdom of our Lord Jesus Christ and the kingdoms of this world." The same sentiments were expressed by the Reverend Adam Gibb in his Display of the Secession Testimony, published in 1774, and by the Antiburgher Synod in the revision of their Testimony. This explicit condemnation of the connection between church and state was one of the principal grounds of the separation of Professor Bruce and Dr M'Crie from the Antiburgher Synod; and the refusal of the Burgher Synod to reverse the act which made this subject a matter of forbearance, was the sole reason why Messrs Willis, Hyslop, and others, renounced their connection with that body. The controversy slumbered during a period of about thirty years from this date; but about the year 1829 it was again resumed, and since that time has increased to such a degree, that the harmony between churchmen and dissenters has been broken up, and the hopes which were formerly cherished of a re-union between the Secession and the Establishment have, for the present at least, been completely extinguished. Proposals were made in 1834, for a union between the Secession and the Synod of Relief, and the measure is still under the consideration of both churches. In the mean time the most friendly intercourse is maintained between them, and, from the harmonious feeling manifested on the subject, in all probability the union will ere long be consummated.

The exposition of ecclesiastical polity, which is given under the article PRESBYTERIAN, applies to the constitution of the United Associate Synod. They have lay-elders, kirk-sessions, and presbyteries; but instead of a General Assembly, they meet in synod once a year, the synod being their supreme court. They have the same standards and the same confession as the Established Church. They believe that the Holy Scriptures are the sole criterion of truth, and the only rule of faith and manners; and that "the Supreme Judge by which all controversies of religion are to be determined, and all the decrees of councils, opinions of ancient writers, doctrines of men and private spirits, are to be examined, and in whose sentence we are to rest, can be no other than the Holy Spirit speaking in the Scriptures." They are fully persuaded, however, that the standards of the Church of Scotland exhibit a just and consistent view of the meaning and design of the Holy Scriptures with regard to doctrine, worship, government, and discipline. They therefore hold the Westminster Confession of Faith, the Larger and Shorter Catechisms, as expressive of the sense in which they understand the Scriptures; and they so far differ from the dissenters in England, that they hold these standards to be not only articles of peace, and a test of orthodoxy, but as a bond of union and fellowship. They consider a simple declaration of adherence to the Scriptures as too equivocal a proof of unity in sentiment, because Arians, Socinians, and Arminians make such a confession of their faith, while they retain sentiments which, they (the Seceders) apprehend, are subversive of the great doctrines of the gospel. They believe that Jesus Christ is the only King and Head of the Church, which is his body; that it is his sole prerogative to enact laws for the government of his kingdom, which is not of this world; and that the church is not possessed of a legislative, but only of an executive power, to be exercised in explaining and applying to their proper objects and ends those laws which Christ has published in the Scriptures. Those doctrines which they teach relative to faith and practice are exhibited at great length in an explanation of the Westminster Assembly's Shorter Catechism, by way of question and answer, composed chiefly by the late Mr Fisher of Glasgow, and published by desire of the synod. They catechise their hearers publicly, and visit them from house to house once every year.

In many of their congregations they celebrate the Lord's Supper four times, in the remainder twice in the year; and they examine their young people strictly concerning their knowledge of the principles of religion previously to their admission to that sacrament. They will permit none to partake of the ordinance of the Lord's Supper who are ignorant of the principles of the gospel, or who are scandalous and immoral in their lives. They condemn private baptism, nor will they admit those who are grossly ignorant and profane to be sponsors for their children. They never accept a sum of money as a commutation for any offence; and those of the delinquents who do not submit to adequate censure are publicly declared to be fugitives from discipline, and are expelled the society. They condemn all clandestine and irregular marriages, nor will they marry any person unless the banns of marriage have been regularly proclaimed in the parish church.

Believing that the people have a natural right to choose their own pastors, the settlement of their ministers always proceeds upon a popular election, and the candidate who is elected by the majority of the communicants is ordained among them. Convinced that a charge of souls is a trust of the greatest importance, they carefully watch over the morals of their students, and direct them to such a course of reading and study as they judge most proper to qualify them for the profitable discharge of the pastoral duties. At the ordination of their ministers, they use a formula nearly of the same kind with that of the Established Church, which their ministers are bound to subscribe when called to it; and if any of them teach doctrines contrary to the Scriptures or the Westminster Confession of Faith, they are sure to be expelled from their communion. It must be noticed, however, that they are not required to approve of any thing in the standards of the church which teaches compulsory or persecuting and intolerant principles in religion.

The education of candidates for the ministry has always been reckoned a matter of the greatest importance by the Secession Church. The course of study is very nearly the same as that adopted by the Establishment. Students, before being admitted to the Theological Hall, must attend at least three years at one of the universities; and the course of preparatory study required of them includes Latin, Greek, Logic, Moral Philosophy, and Mathematics; a knowledge of Hebrew is also required, so that they may be enabled to enter on the critical study of the Old Testament Scriptures as soon as they commence their course of theology. The study of natural philosophy may be deferred till after commencing the study of divinity; but students must produce the certificate of the professor of that science, and be examined as to their proficiency in it, either before admission to the Divinity Hall, or immediately after their first session in it. And it is strongly recommended to them to attend also such classes as they may have access to for the study of geology, chemistry, and other branches of physical science. Students who have a view to the Christian ministry are examined by the presbyteries at the close of each session, that their proficiency may be ascertained, and that they may be prevented from advancing to the higher branches of study till they have acquired a competent knowledge of those which precede them. During the whole course of the student's education, his improvement in personal religion is kept steadily in view. Before he is encouraged to prosecute preparatory studies, strict inquiry is made into his piety, as well as his talents and capability of acquirement; his progress in personal religion as well as in literature is constantly watched over; and he cannot be admitted into the Divinity Hall till he is a member in full communion with the Secession Church.

The Secession has four professors of divinity, each giving instruction in one great department of theological science, or explanatory of the duties of the Christian ministry. 1. The professor of biblical literature, whose duty it is to give a course of lectures on the history, evidence, and interpretation of the sacred books; to direct the reading of the students, and to examine them on these subjects; to read to them portions of the original Scriptures critically, and to require from them explicatory and critical exercises. 2. The professor of exegetical theology, who gives lectures and conducts examinations on one or more of the books of the

Old Testament, the gospel history, the Acts of the Apostles, and one or more of the doctrinal epistles; and who also gives a view of the divine dispensations, as these are detailed in the Holy Scriptures. The course of the present professor embraces a critical exposition of the principal prophecies of the Messiah, the doctrines of Jesus Christ, and the Epistles to the Romans, Galatians, and Hebrews. 3. The professor of systematic theology. 4. The professor of pastoral theology and ecclesiastical history, whose duty it is to explain the qualifications of the ministerial character, and the duties of the pastoral office; and to give instruction in all the services which, as teachers or rulers in the church, ministers are called upon to perform, such as conducting the public devotions of the church, the composition and delivery of pulpit discourses, ministerial visitation of families, public catechising, visitation of the sick, the government and discipline of the church, giving also an abstract of ecclesiastical history. The term of study is five years, and the duration of the annual session two months; and it is rendered imperative on students to attend the whole time. They are usually from five to six hours a day in the classroom. For the first and second sessions of their attendance at the hall, they are committed to the care of the professor of biblical literature and exegetical theology, and the professors of systematic and pastoral theology during the last three years of their course. During the vacation the students are under the superintendence of their respective presbyteries, who meet and converse with them as to their progress in their studies, and hear and criticise their trial discourses. The examinations and exercises prescribed on trials for license and ordination are much the same as in the Established Church.

The Secession has produced a respectable proportion of authors distinguished in various departments of literary pursuit. To say nothing of living authors, the works of Dr Jamieson, the profound and ingenious author of the Scottish Dictionary, and of several learned defences of some of the fundamental principles of religion, entitle him to a place among the distinguished men of his age and country; and the writings of the founders of the Secession, and of Lawson, Dick, Belfrage, Pollock, and others, are well known and highly esteemed in religious and literary circles.

The United Associate Synod now comprehends twenty-two presbyteries, composed of 361 congregations, exclusive of missionary stations both at home and abroad. The following statement will show the regular and steady progress which it has made during the period of one hundred and six years which has elapsed since its origin.

"When the Associate Presbytery was first constituted by the fathers of the Secession, on the 6th of December 1733, the number of the brethren who took this important step amounted only to *four*.

"When the General Assembly pronounced sentence of deposition on the members of the Associate Presbytery on the 15th of May 1740, their number had increased to *eight*.

"Five years after this, when the Associate Presbytery constituted itself into a synod, on the first Tuesday of March 1745, the number of ministers amounted to *twenty-six*.

"When the division occasioned by the burgess oath controversy took place, on the 9th of April 1747, the number had increased to *thirty-two*.

"When the re-union was accomplished, on the 5th of September 1820, the number of ministers belonging to the two synods that were united on that occasion amounted to *two hundred and sixty-two*.

"Since that event took place a period of nineteen years has elapsed, and the number of ordained ministers who are members of the United Associate Synod amounts at the present period to *three hundred and fifty-seven*, being an increase, since the re-union, of nearly *one hundred* ministers."

From accurate returns made by the different congregations, it has been ascertained that the population connected with the Secession Church, including young and old, amounts to 261,345; the number of communicants is 126,070; the sabbath-schools and classes, 716; the number of scholars, 37,612. The average number of persons connected with each congregation is 730, the average number of communicants is 349. The stipends of the ministers vary from L.70 to L.450. The average paid to each minister, exclusive of sacramental expenses, is L.131. In the country, in addition to the stipend, the minister is generally furnished with a dwelling-house. None of the ministers have or ever had a legal bond securing their incomes.

Annual amount of stipends in Secession Church..	L.47,315
Annual allowance for the poor..........................	4,011
Collected for missions by congregational associations	11,042
Annual allowance for sacramental expenses..........	3,610
Annual collection for synod fund..........................	760
Total amount collected annually by the Secession Church..	66,728[1]

A considerable number of missionaries and catechists are maintained in Canada, Jamaica, and other places, either by the synod or by individual congregations in connection with the Secession Church; and many congregations, particularly in the larger towns, support one or more local missionaries at their own expense.

The Presbyterian Synod of Ireland in connection with the United Associate Synod comprehends nine presbyteries and 134 congregations. Proposals are at present making for a union between this body and the Synod of Ulster. The Synod of Nova Scotia contains five presbyteries and twenty-four congregations.

Associate Synod of Original Seceders. This body separated from the Antiburgher Synod in 1806, and formed themselves into a distinct presbytery, called at first *The Constitutional Associate Presbytery*; but after their junction with the few ministers who refused to accede to the union of the Burghers and Antiburghers in 1820, they assumed the name of *The Associate Synod of Original Seceders.* This body now extends to four presbyteries, comprehending thirty-six congregations. They have a professor of divinity of their own, and, with the exception of their opinion respecting the interference of the magistrate in religious matters, they are identical in their leading principles with the United Associate Synod. The late Dr M'Crie, the able and learned biographer of Knox and Melville, was a minister of this body.

Original Burgher Associate Synod. In our history of the Secession Church we gave a brief statement of the controversy which led to the separation of this body from her communion. They extended latterly to four presbyteries, including forty-two congregations. A short time ago, however, they made a formal application to be received into the communion of the Established Church. The proposal met with a favourable reception from the General Assembly, and at the meeting of the Burgher Synod in 1839 a majority of the members agreed to accept of the terms offered by the Assembly, and have accordingly returned into the bosom of the national church. The minority seem as yet not to have determined as to the course which they will pursue.

[1] These, and a variety of other interesting details, will be found in Mackerrow's valuable History of the Secession Church.

SECHELLES, a cluster of high, rocky, and, generally speaking, barren islands, in the Indian Ocean, only three of which are inhabited. Cotton is the only product. There are twelve smaller islands, and as many islets or rocks, besides the larger ones. They abound in turtle, oysters, and particularly cocoa-nuts, which are imported by the inhabitants of the Mauritius. There are six decked vessels which belong to the inhabitants. Lat. 4. to 5. S.

SECKENDORF, Guy Louis de, a very learned German, descended from an ancient and noble family, was born at Aurach, in Franconia, in 1626. He was a good linguist, learned in law, history, and divinity, and is said to have been a tolerable painter and engraver. He was honourably employed by several of the German princes; and died counsellor of state to Frederick III., elector of Brandenburg, and chancellor of the university of Halle, in 1692. He wrote many books, particularly a history and defence of the Lutheran religion, in Latin, in two volumes folio, Frankfort, 1602.

SECKER, Thomas, a learned and respectable prelate of the Church of England, was born in 1693, at a village called Sibthorn, in the vale of Belvoir, in Nottinghamshire. His father was a Protestant dissenter, a pious, virtuous, and sensible man, who, having a small paternal fortune, followed no profession. His mother was the daughter of Mr Brough, a substantial gentleman farmer of Shelton, in the same county. He received his education at several private schools and academies in the country, being obliged, by various accidents, to change frequently his masters.

Notwithstanding this disadvantage, he had at the age of nineteen not only made considerable progress in Greek and Latin, and read the best writers in both languages, but had acquired a knowledge of French, Hebrew, Chaldaic, and Syriac, had learned geography, logic, algebra, geometry, conic sections, and gone through a course of lectures on Jewish antiquities and other points, preparatory to the critical study of the Bible. He had been destined by his father for orders amongst the dissenters. With this view, during the latter years of his education, his studies were chiefly turned towards divinity, in which he had made such advances, that by the time he was twenty-three he had carefully read a great part of the Scriptures, particularly the New Testament, in the original, and the best comments upon it; Eusebius's Ecclesiastical History, the Apostolical Fathers, Whiston's Primitive Christianity, and the principal writers for and against ministerial and lay conformity. But though the result of these inquiries was a well-grounded belief of the Christian revelation, yet not being at that time able to decide on some abstruse speculative doctrines, nor to determine absolutely what communion he should embrace, he resolved, like a wise and honest man, to pursue some profession, which should leave him at liberty to weigh those things more maturely in his thoughts, and not oblige him to declare or teach publicly opinions which were not yet thoroughly settled in his own mind.

In 1716, therefore, he applied himself to the study of physic, and after gaining all the medical knowledge he could, by reading the usual preparatory books, and attending the best lectures during that and the following winter in London, in order to improve himself farther, he went to Paris in January 1719. There he lodged in the same house with the celebrated anatomist Mr Winslow, whose lectures he attended, as he did those of the materia medica, chemistry, and botany, at the King's Gardens. He saw the operations of surgery at the Hôtel Dieu, and attended also for some time M. Gregoire the accoucheur, but without any design of ever practising that or any other branch of surgery. Here he became acquainted with Mr Martin Benson, afterwards bishop of Gloucester, one of the most agreeable and virtuous men of his time, with whom he quickly became connected, and not many years afterwards was united by the strictest bonds of affinity as well as affection.

During the whole of Mr Secker's continuance at Paris, he kept up a constant correspondence with Mr Joseph Butler, afterwards bishop of Durham, with whom he became acquainted at the academy of Mr Jones, which was kept first at Gloucester, and afterwards at Tewkesbury. Mr Butler having been appointed preacher at the Rolls on the recommendation of Dr Clarke, and of Mr Edward Talbot, son of Bishop Talbot, he now took occasion to mention his friend Mr Secker, without Secker's knowledge, to Mr Talbot, who promised, in case he chose to take orders in the Church of England, to engage the bishop his father to provide for him. This was communicated to Mr Secker in a letter from Mr Butler about the beginning of May 1720. He had not at that time come to any resolution of quitting the study of physic; but he began to foresee many obstacles to his pursuing that profession; and having never discontinued his application to theology, his former difficulties with regard to conformity and some other doubtful points had gradually lessened, as his judgment became stronger and his reading and knowledge more extensive. It appears also from two of his letters still extant, written from Paris to a friend in England, both of them prior to the date of Mr Butler's letter above mentioned, that he was greatly dissatisfied with the divisions and disturbances which at that particular period prevailed among the dissenters.

In this state of mind Mr Butler's unexpected proposal found him; and he was therefore very well disposed to take it into consideration. After deliberating on the subject of such a change for upwards of two months, he resolved at length to embrace the offer, and for that purpose quitted France about the beginning of August 1720.

On his arrival in England, he was introduced to Mr Talbot, with whom he cultivated a close acquaintance; but it was unfortunately of very short duration; for in the month of December that gentleman died of the small-pox. This was a great shock to all his friends, who had justly conceived the highest expectations of him, but especially to an amiable lady whom he had lately married, and who was very near sinking under so sudden and grievous a stroke. Mr Secker, besides sharing largely in the common grief, had peculiar reason to lament an accident that seemed to put an end to all his hopes; but he had taken his resolution, and he determined to persevere. It was some encouragement to him to find that Mr Talbot had, on his death-bed, recommended him, together with Mr Benson and Mr Butler, to his father's notice. Thus did that excellent young man, for he was but twenty-nine when he died, by his nice discernment of character and his considerate good nature, provide most effectually for the welfare of that church from which he himself was so prematurely snatched away; and at the same time raised up, when he least thought of it, the truest friend and protector to his wife and unborn daughter, who afterwards found in Mr Secker all that tender care and assistance which they could have hoped for from the nearest relation.

It being judged necessary by Mr Secker's friends that he should have a degree at Oxford, and having been informed, that if he should previously take the degree of doctor of physic at Leyden, it would probably help him in obtaining the other, he went and took his degree there in March 1721; and, as part of his exercise for it, he composed and printed a dissertation *De Medicina Statica*, which is still extant, and is thought by the gentlemen of that profession to be a sensible and learned performance. In April the same year, he entered himself a gentleman commoner of Exeter College, Oxford; after which he obtained the degree of bachelor of arts, in consequence of the chancellor's recommendatory letter to the convocation.

He now spent a considerable part of his time in London, where he quickly gained the esteem of some of the most learned and ingenious men of those days, particularly of Dr

Clarke, rector of St James's, and the celebrated Dean Berkeley, afterwards bishop of Cloyne, with whom he every day became more delighted and more closely connected. He paid frequent visits of gratitude and friendship to Mrs Talbot, widow of Mr Edward Talbot, by whom she had a daughter five months after his decease. With her lived Mrs Catharine Benson, sister of Bishop Benson, whom in many respects she greatly resembled. She had been for several years Mrs Talbot's inseparable companion, and was of unspeakable service to her at the time of her husband's death, by exerting all her courage, activity, and good sense, of which she possessed a large share, to support her friend under so great an affliction, and by afterwards attending her sickly infant with the utmost care and tenderness.

Bishop Talbot being in 1721 appointed to the see of Durham, Mr Secker was in 1722 ordained deacon by him in St James's church, and not long afterwards priest in the same place, where he preached his first sermon on 28th of March 1723. The bishop's domestic chaplain was at that time Dr Rundle, a man of warm fancy and very brilliant conversation, but apt sometimes to be carried, by the vivacity of his wit, into indiscreet and ludicrous expressions, which created him enemies, and, upon one occasion, produced disagreeable consequences. With him Mr Secker was soon afterwards associated in the bishop's family, and both were taken down by his lordship to Durham in July 1723.

In the following year the bishop gave Mr Secker the rectory of Houghton-le-Spring. This preferment putting it in his power to fix himself in the world in a manner agreeable to his inclinations, he soon afterwards made a proposal of marriage to Mrs Benson, which being accepted, they were married by Bishop Talbot in 1725. At the earnest request of both, Mrs Talbot and her daughter consented to live with them, and the two families from that time became one.

About this time Bishop Talbot also gave preferments to Mr Butler and Mr Benson, whose rise and progress in the church are here interwoven with the history of Mr Secker. In the winter of 1725–26, Mr Butler first published his incomparable sermons; of which, as Dr Beilby Porteous and Dr Stinton inform us, Mr Secker took pains to render the style more familiar, and the author's meaning more obvious; yet they were by many called obscure. Mr Secker gave his friend the same assistance in that noble work the Analogy of Religion Natural and Revealed.

He now gave up all the time he possibly could to his residence at Houghton, applying himself with alacrity to all the duties of a country clergyman, and supporting an useful and respectable character throughout. Here he would have been content to live and die; here, as he has often been heard to declare, he spent some of the happiest hours of his life; and it was no thought or choice of his own that removed him to a higher and more conspicuous situation. But Mrs Secker's health, which now began to decline, and was thought to be injured by the dampness of the situation, obliged him to think of exchanging it for a more healthy one. Accordingly, an exchange was made through the friendly interposition of Mr Benson, with Dr Finney, prebendary of Durham, and rector of Ryton; and Mr Secker was instituted to Ryton and the prebend on the 3d of June 1727. For the two following years he lived chiefly at Durham, going every week to officiate at Ryton, and spending there two or three months together in the summer.

In July 1732 he was appointed chaplain to the king; for which favour he was indebted to Dr Sherlock, who having heard him preach at Bath, had conceived the highest opinion of his abilities, and had thought them well worthy of being brought forward into public notice. From that time an intimacy commenced between them, and he received from that great prelate many solid proofs of esteem and friendship.

His month of waiting at St James's happened to be August, and on Sunday the 27th of that month he preached before the queen, the king being then abroad. A few days afterwards, her majesty sent for him into her closet, and held a long conversation with him, in the course of which he took an opportunity of mentioning to her his friend Mr Butler. He also, not long after this, on Mr Talbot's being made lord chancellor, found means to have Mr Butler effectually recommended to him for his chaplain. The queen likewise appointed him clerk of her closet; and from this situation he rose, as his talents became more known, to those high dignities which he afterwards attained.

Mr Secker now began to have a public character, and to stand high in the estimation of those who were allowed to be the best judges of merit. He had already given proofs of abilities that plainly indicated the eminence to which he must one day rise as a preacher and a divine; and it was not long before an opportunity offered of placing him in an advantageous point of view. Dr Tyrrwhit, who succeeded Dr Clarke as rector of St James's in 1729, found that preaching in so large a church endangered his health. Bishop Gibson, his father-in-law, therefore proposed to the crown that he should be made residentiary of St Paul's, and that Mr Secker should succeed him in the rectory. This arrangement was so acceptable to those in power, that it was entered into without any difficulty. Mr Secker was instituted rector on the 18th of May 1733; and in the beginning of July went to Oxford to take his degree of doctor of laws, not being of sufficient standing for that of divinity. On this occasion it was that he preached his celebrated Act Sermon, on the advantages and duties of academical education, which was universally allowed to be a masterpiece of sound reasoning and just composition. It was printed at the desire of the heads of houses, quickly passed through several editions, and is now to be found in the second collection of Occasional Sermons, published by himself in 1766.

It was thought that the reputation he acquired by this sermon contributed not a little towards that promotion which very soon followed its publication. For in December 1734, he received a very unexpected notice from Bishop Gibson, that the king had fixed on him for the see of Bristol. Dr Benson was about the same time appointed to the see of Gloucester, as was Dr Fleming to that of Carlisle; and the three new bishops were all consecrated together in Lambeth chapel, on the 19th of January 1734–1735, the consecration sermon being preached by Dr Thomas, afterwards bishop of Winchester.

The honours to which Dr Secker was thus raised in the prime of life did not in the least abate his diligence and attention. He drew up, for the use of his parishioners, an admirable course of Lectures on the Church Catechism, and not only read them once every week on the usual days, but also every Sunday evening, either at the church or one of the chapels belonging to it.

The sermons which he, at the same time, composed, were truly excellent and original. His faculties were now in their full vigour, and he had an audience to speak before which rendered the utmost exertion of them necessary. In 1737, he succeeded to the see of Oxford, on the promotion of Dr Potter to that of Canterbury, then vacant by the death of Archbishop Wake. In 1750, he was installed dean of St Paul's, for which he gave in exchange the rectory of St James's and his prebend of Durham. Having now more leisure both to prosecute his own studies and to encourage those of others, he gave Dr Church considerable assistance in his First and Second Vindication of the Miraculous Powers, against Mr Middleton; and he was of equal use to him in his Analysis of Lord Bolingbroke's Works. About the same time began Archdeacon Sharp's controversy with the followers of Mr Hutchinson, which

Second || Second Sight.

was carried on to the end of the year 1755. Bishop Secker, we are told, read over all Dr Sharp's papers, amounting to three volumes octavo, and corrected and improved them throughout. But the ease which this change of situation gave him was soon disturbed by a heavy and unexpected stroke, namely, the loss of his three friends, Bishops Butler, Benson, and Berkeley, who were all cut off within the space of one year.

On the death of Archbishop Hutton, he was promoted to the see of Canterbury, and was confirmed at Bow-church, on the 21st of April 1758. He had never once throughout his whole life asked preferment for himself, nor shown any unbecoming eagerness for it; and the use he made of his newly-acquired dignity very clearly showed, that rank, and wealth, and power, had no other charms for him, than as they enlarged the sphere of his active and industrious benevolence.

For more than ten years, during which Dr Secker enjoyed the see of Canterbury, he resided constantly at his archiepiscopal house at Lambeth. A few months before his death, the dreadful pains he felt had compelled him to think of trying the Bath waters; but that design was stopped by the fatal accident which put an end to his life. His Grace had been for many years subject to the gout, which, in the latter part of his life, returned with more frequency and violence, and did not go off in a regular manner, but left the parts affected for a long time very weak, and was succeeded by pains in different parts of the body. About a year and a half before he died, after a fit of the gout, he was attacked with a pain in the arm, near the shoulder, and having continued about twelve months, a similar pain seized the upper and outer part of the opposite thigh, and the arm soon became easier.

On Saturday the 30th of July 1768, he was seized, as he sat at dinner, with a sickness at his stomach. He recovered before night; but the next evening, while his physicians were attending, and his servants raising him on his couch, he suddenly cried out that his thigh-bone was broken. The shock was so violent, that the servants perceived the couch to shake under him, and the pain so acute and unexpected, that it overcame the firmness he so remarkably possessed. He lay for some time in great agony; but when the surgeons arrived, and discovered with certainty that the bone was broken, he was perfectly resigned, and never afterwards asked a question about the event. A fever soon ensued. On Tuesday he became lethargic, and continued so until about five o'clock on Wednesday afternoon, when he expired with great calmness, in the seventy-fifth year of his age. On examination, the thigh-bone was found to be carious about four inches in length, and at nearly the same distance from its head. The disease took its rise from the internal part of the bone, and had so entirely destroyed its substance, that nothing remained at the part where it was broken but a portion of its outward integument; and even this had many perforations, one of which was large enough to admit two fingers, and was filled with a fungous substance arising from within the bone. There was no appearance of matter about the caries, and the surrounding parts were in a sound state. It was apparent that the torture which he underwent during the gradual corrosion of this bone must have been inexpressibly great.

SECOND, in *Geometry*, *Chronology*, and other sciences, the sixtieth part of a prime or minute, whether of a degree or of an hour.

SECOND, in *Music*, one of the musical intervals, being only the difference between any sound and the next nearest sound, whether above or below it.

SECOND SIGHT, in Gaelic called *Taisch*, is a mode of seeing superadded to that which nature generally bestows. This gift or faculty, which is neither voluntary nor constant, is in general rather troublesome than agreeable to the possessors of it, who are chiefly to be found among the inhabitants of the Highlands of Scotland, those of the Western Isles, of the Isle of Man, and of Ireland. It is an impression made either by the mind upon the eye, or by the eye upon the mind, by which things distant or future are perceived, and seen as if they were present. A man on a journey far from home falls from his horse; another, who is perhaps at work about the house, sees him bleeding on the ground, commonly with a landscape of the place where the accident befalls him. Another seer, driving home his cattle, or wandering in idleness, or musing in the sunshine, is suddenly surprised by the appearance of a bridal ceremony, or funeral procession, and counts the attendants or mourners, of whom, if he knows them, he relates the names, but if he knows them not, he can describe the dresses. Things distant are seen at the instant they happen.

Second Sight.

Of things future, Johnson says that he knows no rule pretended to for determining the time between the sight and the event; but we are informed by Mr Grose, that in general the time of accomplishment bears some relation to the time of the day in which the impressions are received. Thus visions seen early in the morning, which seldom happens, will be much sooner accomplished than those appearing at noon; and those seen at noon will take place in a much shorter time than those happening at night. Sometimes the accomplishment of the latter does not fall out within a year or more.

These visions are not confined to solemn or important events, nor is it true, as is commonly reported, that to the second sight nothing is presented but phantoms of evil. The future visit of a mountebank or a piper, a plentiful draught of fish, the arrival of common travellers, or, if possible, still more trifling matters than these, are foreseen by the seers. A gentleman told Dr Johnson, that when he had once gone far from his own island, one of his labouring servants predicted his return, and described the livery of his attendant, which he had never worn at home, and which had been, without any previous design, occasionally given him.

Dr Beattie of Aberdeen gives the following account of this imaginary gift. The Highlands of Scotland are a picturesque but a melancholy country. Long tracts of mountainous desert, covered with dark heath, and often obscured by misty weather; narrow valleys, thinly inhabited, and bounded by precipices resounding with the fall of torrents; a soil so rugged, and a climate so dreary, as in many parts to admit neither the amusements of pasturage nor the labours of agriculture; the mournful dashing of waves along the friths and lakes that intersect the country; the portentous noises which every change of the wind and every increase or diminution of the waters is apt to raise in a lonely region full of echoes and rocks and caverns; the grotesque and ghastly appearance of such a landscape by the light of the moon; objects like these diffuse a gloom over the fancy, which may be compatible enough with occasional and social merriment, but cannot fail to tincture the thoughts of a native in the hour of silence and solitude. If these people, notwithstanding their reformation in religion, and more frequent intercourse with strangers, do still retain many of their old superstitions, we need not doubt but in former times they must have been much more enslaved to the horrors of imagination, when beset with the bugbears of Popery and Paganism. Most of their superstitions are of a melancholy cast. That of Second Sight, by which some are still supposed to be haunted, is considered by themselves as a misfortune, on account of the many dreadful images it is said to obtrude upon the fancy. It is said that some of the Alpine regions do likewise lay claim to a sort of second sight. Nor is it wonderful, that persons of a lively imagination, immured in deep solitude, and surrounded with the stupendous scenery of clouds, precipices, and torrents, should dream, even when they think themselves awake, of those few striking ideas with which their lonely lives are diversified; of corpses, funeral processions, and other subjects of terror; or of marriages, the arrival of strangers, and such like matters of more agreeable curiosity.

Let it be observed, also, that the ancient Highlanders of Scotland had hardly any other way of supporting themselves than by hunting, fishing, or war, professions which are continually exposed to fatal accidents; and hence, no doubt, additional horrors would often haunt their solitude, and a deeper gloom overshadow the imagination even of the hardiest native.

A treatise on this subject was published in the year 1762, in which many tales were told of persons whom the author believed to have been favoured, or haunted, with these illuminations; but most of the tales were trifling and ridiculous, and the whole work betrayed, on the part of the compiler, the most extreme credulity.

That any of these visionaries are apt to be swayed in their declarations by sinister views, we will not say; but this may be alleged with confidence, that none but ignorant people pretend to be gifted in this way; and in them it may be nothing more, perhaps, than short fits of sudden sleep or drowsiness, attended with lively dreams, and arising from some bodily disorder, the effect of idleness, low spirits, or a gloomy imagination. For it is admitted, even by the most credulous Highlanders, that as knowledge and industry are propagated in their country, the second sight disappears in proportion; and nobody ever laid claim to the faculty who was much employed in the intercourse of social life.[1] Nor is it at all extraordinary that one should have the appearance of being awake, and should even think one's self so, during those fits of dozing; that they should come on suddenly, and while one is engaged in some business. The same thing happens in persons much fatigued, or long kept awake, who frequently fall asleep for a moment, or for a long space, while they are standing, or walking, or riding on horseback. Add but a lively dream to this slumber, and take away the consciousness of having been asleep, and a superstitious man may easily mistake his dream for a waking vision; which, however, is soon forgotten when no subsequent occurrence recalls it to his memory, but which, if it shall be thought to resemble any future event, exalts the poor dreamer into a Highland prophet. This conceit makes him more recluse and more melancholy than ever, and so feeds his disease, and multiplies his visions, which, if they are not dissipated by business or society, may continue to haunt him as long as he lives, and which, in their progress through the neighbourhood, receive some new tinctures of the marvellous from every mouth that promotes their circulation. As to the prophetical nature of this second sight, it cannot be admitted at all. That the Deity should work a miracle in order to give intimation of the frivolous things of which these tales are composed, the arrival of a stranger, the nailing of a coffin, or the colour of a suit of clothes; and that these intimations should be given for no end, and to those persons only who are idle and solitary, who speak Gaelic, or who live among mountains and deserts; is like nothing in nature or providence that we are acquainted with, and must therefore, unless it were confirmed by satisfactory proof, be rejected as absurd and incredible.

To these objections Dr Johnson replies, that by presuming to determine what is fit and what is beneficial, they presuppose more knowledge of the universal system than man has attained, and therefore depend upon principles too complicated and extensive for our comprehension; that there can be no security in the consequence when the premises are not understood; that the second sight is only wonderful because it is rare, for, considered in itself, it involves no greater difficulty than dreams, or perhaps than the regular exercise of the cogitative faculty; that a general opinion of communicative impulses, or visionary representations, has prevailed in all ages and among all nations; that particular instances have been given, with such evidence as neither Bacon nor Bayle has been able to resist; that sudden impressions, which the event has verified, have been felt by more than own or publish them; that the second sight of the Hebrides implies only the local frequency of a power which is nowhere totally unknown; and that where we are unable to decide by antecedent reason, we must be content to yield to the force of testimony. By the pretension to second sight, no profit was ever sought or gained. It is an involuntary affection, in which neither hope nor fear are known to have any part. Those who profess to feel it do not boast of it as a privilege, nor are considered by others as advantageously distinguished. They have no temptation to feign, and their hearers have no motive to encourage the imposture.

SECT, a collective term, comprehending all those who follow the doctrines and opinions of some famous divine, philosopher, or other person.

SECTION, in general, denotes a part of a divided thing, or the division itself. Such, particularly, are the subdivisions of a chapter, called also *paragraphs* and *articles*. The mark of a section is §.

Section, in *Geometry*, denotes a side or surface of a body or figure cut off by another, or the place where lines, planes, and the like, cut each other.

SECTOR, in *Geometry*, is a part of a circle comprehended between two radii and an arc of the circle.

Sector is also a mathematical instrument, of use in finding the proportion between quantities of the same kind; as between lines and lines, surfaces and surfaces, &c. whence the French call it the *compass of proportion*. The great advantage of the sector above the common scales is, that it is made so as to fit all radii and all scales. By the lines of chords, sines, &c. upon the sector, we have lines of chords, sines, &c. to any radius between the length and breadth of the sector when open.

The sector is supposed to have been invented by Guido Baldo, or Ubaldo, about the year 1568. The first printed account of it was in 1584, by Gaspar Mordente, at Antwerp, who says that his brother, Fabricius Mordente, invented it in 1554. Treatises on its use have been written by Daniel Specle at Strasburg in 1589; also by Thomas Hood at London in 1598, and by Lewin Hulse at Frankfort-on-the-Maine in 1603, who says that it was invented long before by Justus Byrgius. But the honour of the invention was claimed by Galileo, who wrote on its use in 1607, and by Balthasar Capra of Milan. There are also treatises on it by our countrymen Gunter, Forster, and others.

Before the invention of logarithms, practical men were more easily contented with approximate solutions than they are at present. Now, however, any question that can be resolved by the sector can be about as readily answered by the smallest table of logarithms, and with perfect certainty, as far as the table extends. Hence it is that the sector is not much used, although it is commonly reckoned one of a complete set of mathematical instruments.

For treatises on its use, see Bion on Mathematical Instruments, translated by Stone; Robertson's Treatise on Mathematical Instruments; and Adams's Geometrical Essays.

Any one possessing a sector will easily understand its theory and use from the 14th problem of the fifth section of our treatise on GEOMETRY, where it is taught how to find a fourth proportional to three given lines.

---

[1] This, however, is denied by Johnson, who affirms that the islanders of all degrees, whether of rank or understanding, universally admit it; except the ministers, who, according to him, reject it, in consequence of a system, against conviction. He affirms, too, that in 1773, there was in the Hebrides a second-sighted gentleman, who complained of the terrors to which he was exposed.

SECTOR of a Sphere is the solid generated by the revolution of the sector of a circle about one of its radii; the other radius describing the surface of a cone, and the circular arc a circular portion of the surface of the sphere of the same radius. Hence the spherical sector consists of a right cone, and of a segment of the sphere having the same common base with the cone. The solid content will therefore be found by multiplying the base or spherical surface by the radius of the sphere, and taking one third of the product.

SECTOR of an Ellipse or Hyperbola, is the space contained by any two semidiameters, and the arc of the curve between them.

Astronomical SECTOR, or Equatorial SECTOR, an instrument for taking the difference of right ascensions and declinations of such stars as, on account of their great difference of declinations, will not pass through a fixed telescope. There is an instrument of this kind in the observatory at Greenwich, and it is described in Vince's Practical Astronomy.

Zenith SECTOR, an instrument employed in extensive trigonometrical surveys. Its use is to determine with great accuracy the zenith distances of stars whose declinations differ but little from the latitude of an observer. A very fine instrument of this kind, constructed by Ramsden, is now using in the trigonometrical survey of Britain, and is fully described and figured in the Transactions of the Royal Society of London for 1803.

SECULAR, that which relates to affairs of the present world, in which sense the word stands opposed to *spiritual* and *ecclesiastical.*

SECULAR is more peculiarly used for a person who lives at liberty in the world, not shut up in a monastery, nor bound by vows, or subjected to the particular rules of any religious community; in which sense it stands opposed to *regular.* The Catholic clergy are divided into secular and regular; of which the latter are bound by monastic rules, the former not.

SECULAR Games, in *Antiquity,* solemn games held among the Romans once in an age.

These games lasted three days and as many nights, during which time sacrifices were performed, and theatrical shows exhibited, with combats and sports in the circus. The occasion of these games, according to Valerius Maximus, was to stop the progress of a plague. Valerius Publicola was the first who celebrated them at Rome, in the year of the city 245. The whole world was invited by a herald to a feast which they had never seen before, nor ever should see again. Some days before the games began, the quindecemviri, in the Capitol and in the Palatine temple, distributed to the people purifying compositions of various kinds. Thence the populace passed to Diana's temple on the Aventine Mount, with wheat, barley, and oats, as an offering. After this whole nights were spent in devotion to the Destinies. When the time of the games was fully come, the people assembled in the Campus Martius, and sacrificed to Jupiter, Juno, Apollo, Latona, Diana, the Parcæ, Ceres, Pluto, and Proserpine. On the first night of the feast, the emperor, with the quindecemviri, caused three altars to be erected on the banks of the Tiber, which were sprinkled with the blood of three lambs, and then proceeded to regular sacrifice. A space was next marked out for a theatre, which was illuminated with innumerable flambeaux and fires. Here they sung hymns, and celebrated all kinds of sports. On the day afterwards, having offered victims at the Capitol, they went to the Campus Martius, and celebrated sports in honour of Apollo and Diana. These lasted until next day, when the noble matrons, at the hour appointed by the oracle, went to the Capitol to sing hymns to Jupiter. On the third day, which concluded the solemnity, twenty-seven boys, and as many girls, sung, in the temple of Palatine Apollo, hymns and verses in Greek and Latin, to recommend the city to the protection of those deities whom they designed particularly to honour by their sacrifices. The inimitable *Carmen Seculare* of Horace was composed for this last day, in the Secular Games celebrated by Augustus.

It has been much disputed whether these games were held every hundred or every hundred and ten years. Valerius Antius, Varro, and Livy, are quoted in support of the former opinion. In favour of the latter may be produced the quindecemviral registers, the edicts of Augustus, and the words of Horace in the secular poem, "Certus undenos decies per annos."

It was a general belief, that the girls who bore a part in the song should be soonest married; and that the children who did not dance and sing at the coming of Apollo should die unmarried, and at an early period of life.

SECULARIZATION, the act of converting a regular person, place, or benefice, into a secular one. Almost all the cathedral churches were anciently regular, that is, the canons were religious; but they have been since secularized. For the secularization of a regular church, there is required the authority of the pope, that of the prince, the bishop of the place, the patron, and even the consent of the people. Religious that want to be released from their vow, obtain briefs of secularization from the pope.

SECUNDRA, a town of Hindustan, in the province of Agra, and district of Furrukabad, forty-four miles north-east from Agra. Long. 78. 21. E. Lat. 27. 45. N. It is also a town of Delhi, in the district of Merat, twenty-eight miles south-east from the city of Delhi. Long. 77. 34. E. Lat. 28. 38. N. Likewise a town in the province of Agra, district of Etaweh, on the Jumna, forty-seven miles from the town of Etaweh. Long. 79. 35. E. Lat. 26. 23. N.

SECUNDUS, JOANNES NICOLAIUS, an elegant writer of Latin poetry, was born at the Hague in the year 1511. His descent was from an ancient and honourable family in the Netherlands; and his father Nicolaus Everardus, who was born in the neighbourhood of Middleburg, seems to have been high in the favour of the Emperor Charles V., as he was employed by that monarch in several stations of considerable importance. We find him first a member of the grand parliament or council of Mechelen, afterwards president of the states of Holland and Zealand at the Hague, and lastly holding a similar office at Mechelen, where he died on the 5th of August 1532, aged seventy.

These various employments did not occupy the whole of Everardus's time. Notwithstanding the multiplicity of his business, he found leisure to cultivate letters with great success, and even to act as preceptor to his own children, who were five sons and three daughters. They all took the name of Nicolaii from their father; but on what account our author was called Secundus is not known. It could not be from the order of his birth, for he was the youngest son. Perhaps the name was not given him till he became eminent; and then, according to the fashion of the age, it might have arisen from some pun, such as his being *Poetarum nemini Secundus.* Poetry, however, was by no means the profession which his father wished him to follow. He intended him for the law, and, when he could no longer direct his studies himself, placed him under the care of Jacobus Valeardus. This man is said to have been every way well qualified to discharge the important trust which was committed to him; and he certainly gained the affection of his pupil, who, in one of his poems, mentions the death of Valeardus with every appearance of unfeigned sorrow. Another tutor was soon provided; but it does not appear that Secundus devoted much of his time to legal pursuits. Poetry, and the sister arts of painting and sculpture, had engaged his mind at a very early period; and the imagination, on which these lay hold, can with difficulty submit to the dry study of musty civilians. Secundus is said to have written verses when but ten years old; and from the vast quantity which he left behind him, we have reason to conclude that such writing constituted his principal employment. He found time, however, to carve figures of all his own family, of his mistresses, of the Emperor Charles V., of several eminent personages of those times, and of many of his intimate friends; and in the last edition of his works, published by Scriverius, at Leyden, 1631, there is a print of one of his mistresses with this inscription around it: *Vatis amatoris Julia sculpta manu.*

Secundus having nearly attained the age of twenty-one, and being determined, as it would seem, to comply as far as possible with the wishes of his father, quitted Mechelen, and went to France, where, at Bourges, a city in the Orleannois, he studied the civil law under the celebrated Andreas Alciatus. Alciatus was one of the most learned civilians of that age; but that which undoubtedly endeared him much more to our author, was his general acquaintance with polite literature, and more particularly his taste in poetry. Having studied a year under this eminent professor, and taken his degrees, Secundus returned to Mechelen, where he remained only a very few months. In 1533 he went into Spain with warm recommendations to the Count of Nassau and other persons of high rank; and soon afterwards he became secretary to the cardinal archbishop of Toledo, in a department of business which required no other qualifications than what he possessed in a very eminent degree, a facility in writing with elegance the Latin language. It was during his residence with this cardinal that he wrote his *Basia*, a series of wanton poems, of which the fifth, seventh, and ninth *carmina* of Catullus seem to have given the hint. Secundus was not, however, a servile imitator of Catullus. His expressions seem to be borrowed rather from Tibullus and Propertius; and in the warmth of his descriptions he surpasses every thing that has been written on similar subjects by Catullus, Tibullus, Propertius, C. Gallus, Ovid, or Horace.

In 1535 he accompanied the Emperor Charles V. to the siege of Tunis, but gained few laurels as a soldier. The hardships which were endured at that memorable siege were but little suited to the soft disposition of a votary of Venus and the muses; and upon an enterprise which might have furnished ample matter for an epic poem, it is remarkable that Secundus wrote nothing which has been deemed worthy of preservation. Having returned from his martial expedition, he was sent by the cardinal to Rome to congratulate the pope upon the success of the emperor's arms, but was taken so ill on the road, that he was not able to complete his journey. He was advised to seek, without a moment's delay, the benefit of his native air; and that happily recovered him.

Having now quitted the service of the archbishop of Toledo, Secundus was employed in the same office of secretary by the bishop of Utrecht; and so much had he hitherto distinguished himself by the classical elegance of his compositions, that he was soon called upon to fill the important post of private Latin secretary to the emperor, who was then in Italy. This was the most honourable office to which our author was ever appointed; but before he could enter upon it, death put a stop to his career of glory. Having arrived at Saint Amand, in the district of Tournay, in order to meet, upon business, with the bishop of Utrecht, he was, upon the 8th of October 1536, cut off by a violent fever, in the very flower of his age, not having quite completed his twenty-fifth year. He was interred in the church of the Benedictines, of which his patron the bishop was abbot; and his near relations erected to his memory a marble monument, with a plain Latin inscription.

The works of Secundus have gone through several editions, of which the best and most copious is that of Scriverius already mentioned. It consists of, 1. Julia, eleg. lib. i.; 2. Amores, eleg. lib. ii.; 3. Ad Diversos, eleg. lib. iii.; 4. Basia, styled by the editor *incomparabilis et divinus prorsus liber*; 5. Epigrammata; 6. Odarum liber unus; 7. Epistolarum liber unus; 8. Epistolarum liber alter, heroico carmine scriptus; 9. Funerum liber unus; 10. Sylvæ et Carminum fragmenta; 11. Poemata nonnulla fratrum; 12. Itineraria Secundi tria; 13. Epistolæ totidem, soluta oratione. Of these works it would be superfluous in us to give any character, after the ample testimonies prefixed to them by Lelius Greg. Gyraldus, the elder Scaliger, Theodore Beza, and others equally celebrated in the republic of letters, who all speak of them as excellent.

SECUTORES, a species of gladiators among the Romans, whose arms were a helmet, a shield, and a sword or a leaden bullet. They were armed in this manner, because they had to contend with the retiarii, who were dressed in a short tunic, and bore a three-pointed lance in their left hand, and a net in their right. The retiarius attempted to cast his net over the head of the secutor; and if he succeeded, he drew it together and slew him with his trident; but if he missed his aim, he immediately betook himself to flight, till he could find a second opportunity of entangling his adversary with his net. He was pursued by the secutor, who endeavoured to despatch him in his flight.

Secutores was also a name given to such gladiators as took the place of those that were killed in the combat, or who engaged the conqueror. This post was usually taken by lot.

SEDAN, an arrondissement of the department of the Ardennes, in France, extending over 278 square miles, divided into four cantons and eighty-two communes, with, in the year 1836, 63,233 inhabitants. The capital is the fortified city of the same name, situated on the river Meuse. It is celebrated for its cloth manufactures, especially those of black; and it has also some considerable establishments for making cannon, muskets, and other arms, as well as other kinds of hardware, and china. In the same year its population amounted to 13,719. It was the birthplace of the celebrated Turenne. Long. 4. 52. 31. E. Lat. 49. 22. 29. N.

SEDAN-CHAIR is a covered vehicle for carrying a single person, being suspended by two poles, and borne by two men, who are hence denominated *chairmen*. They were first introduced into London in 1634, when Sir Sanders Duncomb obtained the sole privilege to use, let, and hire a number of the said covered chairs for fourteen years.

SEDASIER, a town of Hindustan, in the province of Mysore, and district of Coorg. In 1799 the troops of Tippoo Sultan were here defeated by the British. It is seven miles north-west of Periapatam.

SEDBERGH, a town in the wapentake of Staincliff and Ewcross, in the west riding of the county of York, 271 miles from London. It is situated on the borders of Westmoreland, at the foot of the Houghill Fells. It has a market, which is held on Thursday. The population amounted in 1821 to 4483, and in 1831 to 4711.

SEDHOUT, a district in the Balaghaut ceded territories, situated principally between the fourteenth and fifteenth degrees of north latitude. It lies immediately within the Eastern Ghauts. It is a rocky and mountainous region, indifferently cultivated, but interspersed with fertile valleys. The chief river is the Pennar, and the principal town is Odegherry. The fortress of Sedhout, the capital of the above district, was taken by Meer Jumla about the year 1650. At this period Sedhout and the adjoining district were celebrated for their diamond mines, which, however, are no longer worked.

SEDITION, among civilians, is used for a factious commotion of the people, or an assembly of a number of citizens without lawful authority, tending to disturb the peace and order of society. This offence is of different kinds. Some seditions more immediately threaten the supreme power, and the subversion of the present constitution of the state; others tend only towards the redress of private grievances. Among the Romans, therefore, it was variously punished, according as its end and tendency threatened greater mischief. (See lib. i. *Cod. de Seditiosis*, and *Mat. de Crimin.* lib. ii. n. 5, *De Læsa Majestate.*) In the punishment, the authors and ringleaders were justly distinguished from those who, with less wicked intention, joined and made part of the multitude.

The same distinction holds in the law of England and in that of Scotland. Some kinds of sedition in England amount to high treason, and come within the statute 25 Edward III. as levying war against the king. And several seditions are mentioned in the Scotch acts of parliament as treasonable (Bayne's Crim. Law of Scotland, p. 33, 34). The law of Scotland makes riotous and tumultuous assemblies a species of sedition. But the law there, as well as in England, is now chiefly regulated by the riot act, made 1 Geo. I.; only it is to be observed, that the proper officers in Scotland to make the proclamation thereby enacted are sheriffs, stewards, and bailies of regalities, or their deputies; magistrates of royal boroughs, and all other inferior judges and magistrates; high and petty constables, or other officers of the peace, in any county, stewartry, city, or town. In that part of the island, the punishment of the offence is any thing short of death which the judges, in their discretion, may appoint.

SEDATIVES, in *Medicine*, a general name for such medicines as weaken the powers of nature, such as blood-letting, cooling salts, purgatives, and the like.

SE-DEFENDENDO, in *Law*, is a plea used for him who is charged with the death of another, by alleging that he was under a necessity of doing what he did in his own defence; as that the other assaulted him in such a manner, that if he had not done what he did, he must have been in hazard of his own life.

SEDLEY, Sir Charles, an English poet and wit, the son of Sir John Sedley of Aylesford in Kent, was born about the year 1639. At the restoration he came to London to join the general jubilee, and commenced wit, courtier, poet, and gallant. He was so much admired, that he became a kind of oracle among the poets; which made King Charles tell him, that nature had given him a patent to be Apollo's viceroy. The productions of his pen were some plays, and several delicately tender amorous poems, in which the softness of the verses was so exquisite, as to be called by the Duke of Buckingham Sedley's witchcraft. Less pleasing opinions, however, have been expressed by others. "There were no marks of genius or true poetry to be descried," say the authors of the *Biographia Britannica;* "the art wholly consisted in raising loose thoughts and lewd desires, without giving any alarm; and so the poison worked gently and irresistibly. Our author, we may be sure, did not escape the infection of his own art, or rather was first tainted himself before he spread the infection to others." A very ingenious writer, however, speaks much more favourably of Sir Charles Sedley's writings. "He studied human nature," says Langhorn in his Effusions, "and was distinguished for the art of making himself agreeable, particularly to the ladies; for the verses of Lord Rochester, beginning with, *Sedley has that prevailing gentle art*, so often quoted, allude not to his writings, but to his personal address." But whilst he thus grew in reputation for wit and in favour with the king, he became poor and debauched; his estate was impaired, and his morals were corrupted. One of his frolics, however, being followed by an indictment and a heavy fine, Sir Charles took a more serious turn, applied himself to business, and became a member of parliament, in which he was a frequent speaker. We find him in the House of Commons in the reign of James II., whose attempts upon the constitution he vigorously withstood; and he was very active in bringing about the Revolution. This was thought more extraordinary, as he had received favours from James. But that prince had taken a fancy to Sir Charles's daughter, though it seems she was not very handsome, and, in consequence of his intrigues with her, he created Miss Sedley countess of Dorchester. This honour, so far from pleasing, greatly shocked Sir Charles. However libertine he himself had been, yet he could not bear the thoughts of his daughter's dishonour; and with regard to her exaltation, he only considered it as rendering her more conspicuously infamous. He therefore conceived a hatred for the king, and from this, as well as other motives, readily joined to dispossess him of the throne. A witty saying of Sedley's, on this occasion, is recorded. "I hate ingratitude," said Sir Charles; "and therefore, as the king has made my daughter a countess, I will endeavour to make his daughter a queen;" meaning the Princess Mary, married to the Prince of Orange, who dispossessed James of the throne at the Revolution. He lived till the beginning of Queen Anne's reign, and his works were printed in two vols. 8vo, 1719.

SEDRE Passage, a narrow channel of the Eastern Seas, on the north coast of Sumatra, between Pulo Nancy and King's Point.

SEDUCTION is the act of tempting and drawing aside from the right path, and comprehends every endeavour to corrupt any individual of the human race. This is the import of the word in its largest and most general sense; but it is commonly employed to express the act of tempting a virtuous woman to part with her chastity.

The seducer of female innocence practises the same stratagems of fraud to get possession of a woman's person, that the swindler employs to get possession of his neighbour's goods or money; yet the law of honour, which pretends to abhor deceit, and which impels its votaries to murder every man who presumes, however justly, to suspect them of fraud, or to question their veracity, applauds the address of a successful intrigue, though it be well known that the seducer could not have obtained his end without swearing to the truth of a thousand falsehoods, and calling upon God to witness promises which he never meant to fulfil.

The law of honour is indeed a very capricious rule, which accommodates itself to the pleasures and conveniences of higher life; but the law of the land, which is enacted for the equal protection of high and low, may be supposed to view the guilt of seduction with a more impartial eye. Yet for this offence, even the laws of this kingdom have provided no other punishment than a pecuniary satisfaction to the injured family; which, in England, can be obtained only by one of the quaintest fictions in the world, by the father's bringing his action against the seducer for the loss of his daughter's service during her pregnancy and nurturing. (See Paley's Moral Philosophy, book iii. part iii. chap. 3.)

The moralist, however, who estimates the merit or demerit of actions, not by laws of human appointment, but by their general consequences as established by the laws of nature, must consider the seducer as a criminal of the deepest guilt. In every civilized country, and in many countries where civilization has made but small progress, the virtue of women is collected as it were into a single point, which they are to guard above all things, as that on which their happiness and reputation wholly depend. At first sight this may appear a capricious regulation; but a moment's reflection will convince us of the contrary. In the married state so much confidence is necessarily reposed in the fidelity of women to the beds of their husbands, and

Seduction.

See Amol ‖ Seebah.

evils so great result from the violation of that fidelity, that whatever contributes in any degree to its preservation, must be agreeable to Him who, in establishing the laws of nature, intended them to be subservient to the real happiness of all his creatures. But nothing contributes so much to preserve the fidelity of wives to their husbands, as the impressing upon the minds of women the highest veneration for the virtue of chastity. She who, when unmarried, has been accustomed to grant favours to different men, will not find it easy, if indeed possible, to resist afterwards the allurements of variety. It is therefore a wise institution, and agreeable to the will of Him who made us, to train up women so that they may look upon the loss of their chastity as the most disgraceful of all crimes; as that which sinks them in the order of society, and robs them of all their value. In this light virtuous women actually look upon the loss of chastity. The importance of that virtue has been so deeply impressed upon their minds, and is so closely associated with the principle of honour, that they cannot think but with abhorrence upon the very deed by which it is lost. He therefore who by fraud and falsehood persuades the unsuspecting girl to deviate in one instance from the honour of the sex, weakens in a great degree her moral principle; and if he reconcile her to a repetition of the crime, he destroys that principle entirely, as she has been taught to consider all other virtues as inferior to that of chastity. Hence it is that the hearts of prostitutes are generally steeled against the miseries of their fellow-creatures; that they lend their aid to the seducer in his practices upon other girls; that they lie, and swear, and steal without compunction; and that too many of them hesitate not to commit murder, if it can serve any selfish purpose of their own.

The loss of virtue, though the greatest that man or woman can sustain, is not the only injury which the seducer brings upon the girl whom he deceives. She cannot at once reconcile herself to prostitution, or even to the loss of character, and whilst a sense of shame remains in her mind, the misery which she suffers must be exquisite. She knows that she has forfeited what in the female character is most valued by both sexes; and she must be under the perpetual dread of a discovery. She cannot even confide in the honour of her seducer, who may reveal her secret in a fit of drunkenness, and thus rob her of her fame as well as of her virtue; and whilst she is in this state of anxious uncertainty, the agony of her mind must be insupportable. That it is so in fact, the many instances of child-murder by unmarried women of every rank leave us no room to doubt. The affection of a mother to her new-born child is one of the strongest and most unequivocal instincts in human nature; and nothing short of the extremity of distress can prompt any one so far to oppose nature as to embrue her hands in the blood of her imploring infant.

Even this deed of horror seldom prevents a detection of the mother's frailty, which is indeed commonly discovered, though no child has been the consequence of her intrigue. He who can seduce is base enough to betray; and assuredly no woman can part with her honour and yet retain any well-grounded hope that her amour shall be kept secret. The villain to whom she surrendered will glory in his victory, if it was with difficulty obtained; and if she surrendered at discretion, her own behaviour will reveal her secret. Her reputation is then irretrievably lost, and no future circumspection will be of the smallest avail to recover it. She will be shunned by the virtuous part of her own sex, and treated as a mere instrument of pleasure by the other. In such circumstances she cannot expect to be married with advantage. She may perhaps be able to captivate the heart of a heedless youth, and prevail upon him to unite his fate to hers, before the delirium of his passion shall give him time for reflection; she may be addressed by a man who is a stranger to her story, and married while he has no suspicion of her secret; or she may be solicited by one of a station inferior to her own, who, though acquainted with every thing that has befallen her, can barter the delicacy of wedded love for some pecuniary advantage. But from none of these marriages can she look for happiness. The delirium which prompted the first will soon vanish, and leave the husband to the bitterness of his own reflections, which can hardly fail to produce cruelty to the wife. Of the secret to which, in the second case, the lover was a stranger, the husband will soon make a discovery, or at least find room for harbouring strong suspicions; and suspicions of having been deceived in a point so delicate have hitherto been uniformly the parents of misery. In the third case, the man married her merely for her money, of which having got the possession, he has no further inducement to treat her with respect. Such are some of the consequences of seduction, even when the person seduced has the good fortune afterwards to get a husband. But this is a fortune which few in her circumstances can reasonably expect. By far the greater part of those who have been defrauded of their virtue by the arts of the seducer sink deeper and deeper into guilt, till they become at last common prostitutes. The public is then deprived of their services as wives and parents; and instead of contributing to the population of the state, and to the sum of domestic felicity, these outcasts of society become seducers in their turn, corrupting the morals of every young man whose appetites they can inflame, and of every young woman whom they can entice to their own practices.

All this complication of evil is produced at first by arts which, if employed to deprive a man of his property, would subject the offender to the execration of his fellow-subjects, and to an ignominious death. But while the forger of a bill is pursued with relentless rigour by the ministers of justice, and the swindler loaded with universal reproach, the man who by fraud and forgery has enticed an innocent girl to gratify his desires at the expense of her virtue, and thus introduced her into a path which must infallibly lead to her own ruin, as well as to repeated injuries to the public at large, is not despised by his own sex, and is too often caressed even by the virtuous part of the other. Yet the loss of property may be easily repaired; whilst the loss of honour is irreparable. It is vain to plead in alleviation of this guilt, that women should be on their guard against the arts of the seducer. Most unquestionably they should; but arts have been used which hardly any degree of caution would have been sufficient to counteract. It may as well be said that the trader should be on his guard against the arts of the forger, and accept of no bill without previously consulting him in whose name it is written. Cases, indeed, occur in trade, in which this caution would be impossible. But he must be little acquainted with the workings of the human heart, who does not know that situations likewise occur in life, in which it is equally impossible for a girl of tenderness and virtue to resist the arts of the man who has completely gained her affections.

SEE AMOL, a small island in the Eastern Seas, near the east coast of Borneo. Long. 118. 48. E. Lat. 5. 27. N.

SEE BANGOG, a small island in the Eastern Seas, near the east coast of Borneo. Long. 118. 24. E. Lat. 4. 18. N.

SEE BEEROO ISLE, an island that lies off the west coast of Sumatra, and is situated principally between the first and second degrees of south latitude, and the ninety-eighth and ninety-ninth of east longitude. It is seventy miles in length by ten in average breadth, and contains a volcano, which renders it conspicuous at a distance.

SEEASSEE ISLE, a small island in the Eastern Seas, one of the Sooloo archipelago. It is a woody island, well supplied with water, and yields many cowries and small baat, named Seeassee.

SEEBAH, a town and district in the Sikh territories, in the province of Lahore, between the thirty-first and thirty-second degrees of north latitude. The district is hilly, and covered with wood; and the town is fortified, being situated a hundred miles east by south from the city of Lahore. Long. 75. 34. E. Lat. 31. 39. N.

SEEBGUNGE, a town of Bengal, in the district of Dinagepoor, eighty-four miles north-north-east from Moorshedabad. Long. 89. 12. E. Lat. 25. 3. N.

SEEDGHUR, a celebrated fortress of Hindustan, in the province of Bejapore, taken, with scarcely any loss, from the Mahrattas in 1818.

SEEDLINGS, among gardeners, denote such roots of gilliflowers and others as come from seed sown; also the young and tender shoots of any plants that are newly sown.

SEEKS, or Sikhs, a religious sect settled at Patna, and so called from a word contained in one of the commandments of their founder, which signifies *learn thou*. In books giving an account of the oriental sects and oriental customs, we find mention made both of the Seeks and the Sikhs; and we are strongly inclined to think that the same tribe is meant to be denominated by both words. If so, however, different authors write very differently of their principles and manners. (See Mr Wilkins's account of them in the Asiatic Researches.)

SEENGHOO, a town of the Birman empire, situated on the banks of the Irrawaddy.

SEEOR, a town of Hindustan, in the Mahratta territories, and province of Malwah, twenty-two miles west by south from Bopal, situated on the small river Rootah Seein. It has a considerable manufactory of striped and chequered muslins.

SEEPARRAN, a small island in the Eastern Seas, near the east coast of Borneo. Long. 118. 23. E. Lat. 4. 8. N.

SEER, a principality of Arabia, in the province of Ommon, extending from Cape Mussendoon, along the shores of the Persian Gulf. This country not long since acknowledged the sovereign authority of the Imam; but the scheich has shaken off this dependence, and is often at war with his former master. His navy is one of the most considerable in the Persian Gulf; his subjects are much employed in navigation, and carry on an extensive trade.

SEERDHUNA, a town of Hindustan, in the province of Delhi, and district of Merat. This place was formerly the residence of Somroo Begum, and the capital of a small principality under her government, about twenty miles in length by twelve in breadth, which, with the town, were assigned to Somroo, who was originally a German, his real name being Walter Reinihard, who went to Bengal and entered the French service, and afterwards that of Gregory, an Armenian, who was high in favour with Cossim Ali, to whom he recommended Somroo. It was this adventurer who massacred the English prisoners at Patna in 1763. He died in 1776, leaving a favourite concubine, who resided at Delhi, under the protection of the British government, in 1807, and invested her property in the East India Company's funds at Calcutta. The district is fertile, producing all kinds of grain, sugar, and cotton. Long. of the town 77. 28. E. Lat. 29. 11. N.

SEERPOOR, a town in the province of Bengal, and district of Raujeshy, seventy-four miles north-east from Moorshedabad. Long. 89. 20. E. Lat. 24. 38. N.

SEES, a city of France, in the department of the Orne, and arrondissement of Alençon. It stands in a fruitful plain on the river Orne, near its source, is the seat of a bishop, and contains 900 houses, with 5860 inhabitants, who are employed in making black lace, hosiery, and cotton goods. Long. 6. 4. 44. E. Lat. 48. 36. 21. N.

SEETACOOND, a town of Bengal, in the district of Chittagong, remarkable for a warm spring, from which issues a flame, which is considered by the ignorant Hindus as an emanation from the deity, and consequently worthy of being worshipped. It is seventeen miles north from Islamabad. Long. 91. 36. E. Lat. 22. 37. N.

SEGALIEN. See Saghalien.

SEGMENT *of a* Circle, in *Geometry*, is that part of the circle which is contained between a chord and an arc of the same circle.

SEGMENTS, Line of, two particular lines on Gunter's sector. They lie between the lines of sines and superficies, and are numbered 5, 6, 7, 8, 9, 10. They represent the diameter of a circle, so divided into 100 parts, that a right line drawn through these parts, and perpendicular to the diameter, shall cut the circle into two segments, the greater of which shall have the same proportion to the whole circle as the parts cut off have to 100.

SEGO. See Bambarra.

SEGORBE, a city of Spain, upon the Palancia, in the province of Valencia, and in the neighbourhood of the Marmor Marsh, with 5000 inhabitants, whose trade consists of a few potteries, and the distillation of brandy.

SEGOVIA, one of the four provinces into which Old Castille, in Spain, is divided. It is generally an open and arid district, with scanty water, and little to merit description, except its capital, and the royal residences of Ildefonso and the Escurial, each of which is described under its appropriate article. The extent of the province is 290 square leagues, and its population amounts to 221,379 souls. The greater part of the province is destined to feed merino flocks, and the largest portion, particularly those with the finest wool, are shorn within it, as the weather is sufficiently warm to enable the sheep to bear that operation without feeling any inconvenience. Though it grows wine, oil, and corn, the harvests are by no means adequate to the consumption, and their wants must be supplied from other lands than their own. It is watered by the Ebro, the Cresma, the Xarama, and the Duraton; and it possesses mineral springs at Cinchon, Caballar, and Bartariejo. It belongs to the captain-generalship of Zamora.

Segovia, a city of Spain, and capital of the province of the same name, in Old Castille. It is situated on the right bank of the river Duero, not far from its source, and near to the ruins of the ancient Roman city of Numantia. Around it are most excellent pastures for sheep, and the wool of the best of the merinos takes its name from this city. The usual quantity of fine wool annually sent from this city is about 2,250,000 lbs., and the management of such extensive concerns necessarily creates considerable trade. There is in this city a manufactory of fine cloths, cassimeres, and other articles composed of the native wool, which is carried on by the government.

The remains of antiquity in this city are, however, the most interesting attractions to all travellers. The aqueduct, of very ancient construction, is yet in perfect preservation, and still conveys the water to the city. It is carried over one of the suburbs or arches, some of which are a hundred and four feet in height; the arches are in double rows, one above the other, and on the uppermost a channel is made, covered with large flag-stones, through which the water runs. It is a wonderful relic of antiquity, on account of the excellence of the masonry, which has withstood the ravages of time for so many centuries. The period of its erection is doubtful. The Spaniards, who delight in tracing every ancient monument to the highest antiquity, ascribe it to Hercules; it is, however, evidently of Roman construction, and none give it a later date than the reign of Trajan. It discovers as yet no marks of decay, and as the city to which it conveys water is on the top of a rock, if it were demolished the inhabitants would be greatly distressed for that necessary of life.

The ancient castle, or alcazar, is another of the curiosities of Segovia. It stands on a rude mass of rocks overlooking the surrounding country, whose base is washed by a rapid and limpid stream, whilst the houses of the city stretch themselves from it in both directions, and terminate in woody declivities. It is an astonishing pile of building, and contains some apartments of stupendous extent. The foundation and the lower part of the walls are obviously of Roman origin, whilst the upper part, and what may be called the keep, are as plainly the execution of the Moors, whose contrivances for shooting their arrows at the heads of assailants, without being themselves subject to annoyance, are in the most perfect preservation. Within this castle is a state-prison, which is well described by Le Sage in his Adventures of Gil Blas. A part of the building is used by the artillery department of government. The mint is below the castle, and furnished with all the machinery requisite for coining money, which is principally set in motion by water.

The cathedral of Segovia is one of the most complete specimens of the later Gothic style of architecture of any religious edifice in Spain. Excepting the antiquities of this celebrated city, the rest deserves little notice. The streets are crooked and narrow. Many of the houses are of wood, and most of them very dirty; and in spite of the great trade carried on in wool by some individuals, an air of poverty pervades the mass of the inhabitants.

SEGOVIA, a town of America, in Terra Firma, and in the province of Venezuela, situated on a river, near a very high mountain, where there are mines of gold. Long. 65. 30. W. Lat. 8. 20. N.

SEGOVIA, a town of Asia, in the island of Manilla, and one of the largest of the Philippines, situated at the north end of the island, 240 miles north of Manilla, and subject to Spain. Long. 120. 50. E. Lat. 18. 36. N.

SEGOVIA, *New*, a town of North America, in New Spain, and in the audiencia of Guatimala, situated on the river Yare, on the confines of the province of Honduras. Long. 84. 30. W. Lat. 13. 25. N.

SEGRE, an arrondissement of the department of the Maine and Loire, in France, extending over $408\frac{2}{3}$ square miles. It is divided into six cantons, and these into seventy-seven communes, and in 1836 contained 58,109 inhabitants. The capital is a small town of the same name, with some trade in linen goods. Its population in 1836 amounted to 2130.

SEGREANT is the herald's word for a griffin when drawn in a leaping position, and displaying his wings as if ready to fly.

SEGUE, in Italian music, is often found before *aria*, *alleluja*, *amen*, and some others, to show that those portions or parts are to be sung immediately after the last note of that part over which it is written; but if these words *si placet*, or *ad libitum*, are joined with it, it signifies that the portions may be sung or not at pleasure.

SEGUIDILLA, the Spanish name of a quick and animated melody in $\frac{3}{4}$ time, much used in Spain in singing and in dancing.

SEGURA, a city of Spain, the capital of a department of the same name, lying between La Mancha and Granada, in the province of Murcia. Near to it rises the river Segura, which traverses the whole province, and falls into the Mediterranean Sea about sixteen miles to the south-west of Alicant. The town is surrounded with walls, and is an episcopal see. It contains 820 houses, and 4000 inhabitants, who are mostly occupied in agriculture, producing wine, fruit, especially figs, and oil. Another town bears the same name in the province of Zaragoza, and department of Daroca. It stands on the river Xiloca, and contains 1800 inhabitants. There is also a Segura in the province of Guipuscoa, and department of St Sebastian, on the banks of the river Oria. It was once fortified, but its works have gone to decay.

SEGWIN, a small territory in Northern Hindustan, situated between Nepaul and Bootan, about the 28th degree of north latitude, and extending along the banks of the river Teesta, which bounds it to the west. In 1792, when the Chinese invaded Nepaul, the rajah of Segwin submitted to become a subject of China; and here accordingly the Chinese established a military post immediately adjoining the dominions of the East India Company in Bengal.

SEIGNIOR, or SIGNIOR, is, in its general signification, the same with lord, but is particularly used for the lord of the fee or of a manor, as seigneur among the feudists is he who grants a fee or benefit out of the land to another; and the reason is, because, having granted away the use and profit of the land, the property or dominion he still retains in himself.

SEIGNIORAGE is a royalty or prerogative of the king, by which he claims an allowance of gold and silver brought in the mass to be exchanged for coin. See COINAGE.

SEIGNIORY is borrowed from the French *seigneurie*, which means *dominatus*, *imperium*, *principatus*, and signifies with us a manor or lordship, *seigniory de sokemans*. *Seigniory in gross* seems to be the title of him who is not lord by means of any manor, but immediately in his own person; as *tenure in capite*, by which one holds of the king, as of his crown, is *seigniory in gross*.

SEINE, one of the departments of the north-eastern part of France, taking its name from the river which passes through it, and containing Paris, the capital of that mighty kingdom. As that city is the most important portion of the department, the account of it in this work comprehends what is most remarkable. It is on every side surrounded by the department of the Seine and Oise, and extends over 47,548 French hectares, equal to $167\frac{1}{6}$ square miles, or 106,983 English acres. It is generally a level district, but intersected with some hills of inconsiderable height. The river Seine receives within the department the navigable river Marne, and the smaller streams of the Ourcq and the Erould. The Canal of St Denis unites the Seine with the Oise; and the Canal of Ourcq, which terminates in a reservoir between La Vilette and La Chapelle, supplies Paris with water, and being navigable, serves to maintain an intercourse between that city and the north of France. The canal is supplied with water from the small streams of the Grisette, the Mai, the Therouanne, and the Beuvronne. The soil is for the most part by nature poor and sandy, but brought to a highly productive state by the vast quantities of manure furnished by the capital, and by the high state of the cultivation, which is mostly garden husbandry, whose products find advantageous markets in the metropolis. There are still some woods preserved, but mostly for the purpose of ornament, and to serve for the recreation of the inhabitants of Paris. The woods of Boulogne and of Vincennes occupy together about six thousand English acres. It is divided into three arrondissements, eight cantons, and eighty-one communes. The population, which includes Paris, amounted in 1821 to 822,171, in 1831 to 935,108, and in 1836 to 1,106,891, of which 909,126 were within the city.

SEINE, *Lower*, a department of the north-west of France, formed out of those northern parts of Upper Normandy which were in ancient times distinguished as the Roumais, Bezin-Normandy, Caux, and Bray. It is bounded on the north by the sea, on the east by the departments of the Somme and of the Oise, on the south by Eure and Calvados, and on the west by the Channel. It is $2144\frac{1}{4}$ square miles in extent, and comprehends five arrondissements, fifty cantons, and 757 communes. The population amounted in 1836 to 720,525 persons, who mostly adhere to the Roman Catholic church; but among them are 55,000 Protestants, having two consistorial and 113 other churches.

The surface is generally level, but intersected by some hills of moderate height, mostly composed of chalk. Towards the east the valleys are widest, and run from east to west. Along the whole coast are chalky cliffs from 150 to 700 feet in height, but interrupted in places by the bays and harbours. The soil is on the whole the most fertile in France, though there are portions of it very unproductive of corn, and generally covered with wood, which woods comprehend one seventh of the whole department. The agriculture is tolerably conducted, but the greater part of it is on the ancient system of a fallow succeeded by two crops of grain. About 340,000 acres are sown with wheat, and about 250,000 with oats, which is a large portion out of the 1,372,302 acres; yet it appears that the corn produced is scarcely equal to the consumption. The best lands are the meadows in the valleys through which the Seine and the other rivers run, and these afford nourishment for numerous herds of cows, which supply both meat and the products of the dairy. It is, however, in the interior of the department that the best breed of cows are to be seen, which are a mixture of the Flanders race, whereas on the coast they are commonly of a much smaller size.

The breed of the ancient Norman horses is now nearly extinct. Those now bred are of a mixed race, and more remarkable for their strength than for their beauty, and are well adapted for the plough, for which they are almost exclusively used. The sheep are numerous, and those of the fine woolled kind have of late years been rapidly on the increase. In the valleys of Arques and of Pouville the mutton is highly valued. In the more woody portions of the department are kept very great numbers of swine, in which the acorns are found of great benefit. Most kinds of fruit are abundant, with the exception of vines; but the deficiency of them is counterbalanced by the great quantity of apples, which are converted into cider, and form a good substitute for wine. The fishery on the sea-coast affords considerable occupation, and a great additional supply of food. The herring-fishery is extensively practised from Dieppe and Fecamp; and from other places on the shore enormous quantities of mackerel are taken, whilst the oyster-fishery employs many hands. The manufacturing industry is very active, especially in the arrondissement of Rouen. Woollen and cotton goods of every kind are made, and the best kinds of machinery are in full exercise. Large establishments exist which provide paper, glass, pottery, and china ware; and on the coast much linen is spun and woven. There are many ship and boat builders; and the cordage and equipments contribute their share to furnish occupation to labourers. There is much internal trade, especially with Paris, by the river Seine. The principal places within the department are Rouen, Havre de Grace, Dieppe, Fecamp, and Yvetot.

Seine *and Marne*, a department of the north of France. It has been formed out of parts of the ancient provinces of the Isle of France and of Champagne, called French Gatinois, and the Upper and Lower Brie. It is bounded on the north by the department of the Oise, on the east by the Aisne and the Marne and Aube, on the south by the Yonne and Loiret, and on the west by the Seine and Oise. It extends over 1981 square miles, is divided into five arrondissements, twenty-nine cantons, and 556 communes, and in 1836 contained 325,881 inhabitants. The capital of the department is the city of Melun, with a population of 6846 inhabitants in 1836. Besides the two rivers from which it is named, it is watered by the Great and Little Morin, the Bouzie, the Yonne, the Essonne, the Yres, the Therouanne, the Beuvronne, and the Otrin, all of whose waters reach the sea through the Seine. The surface is a plain, but intersected by some hills of very moderate height. The soil is fruitful, especially near the principal rivers; and though woods cover more than one tenth of the department, it is the chief granary from whence the capital draws its supply of corn, flour, garden-fruits, and fattened cattle. The rivers abound with fish, and the woods with game. The meadows are of great fertility, yielding abundance of hay and other fodder, and supporting numerous cows, whose dairies supply Paris with the greater part of its milk, butter, and veal, whilst the cheese of Brie has attained great celebrity. It yields some wine, but its quality is only moderate, and does not equal the consumption. There is much manufacturing industry applied to the making of glass, of paper of the best kind, of leather, of steel articles, of hosiery, of linen goods, and of various smaller articles. The chief towns are Coulommiers, Meaux, Fontainebleau, and Provins.

Seine *and Oise*, a department in the north of France. It is bounded on the north by the Eure and the Oise, on the east by the Seine-Marne, on the south by the Loiret, and on the west by the Eure and Loire. It extends over 1970 square miles, is divided into six arrondissements, thirty-six cantons, and 687 communes, and in 1836 contained 449,582 inhabitants, who elect four deputies to the legislative chamber. The chief river is the Seine, with which the Oise is united, and then it receives the waters of the Marne, the Essonne, the Juine, the Ept, and the Maudre, and of the various tributary streams which empty themselves into these rivers. It is generally a level district, with a few ranges of hills of moderate height. The soil is not naturally fertile, but has been rendered productive by careful cultivation, and the abundance of manure, arising from its vicinity to the metropolis. It surrounds the department of the Seine on every side, has easy water-communication with Paris, and, besides, contains within it the city of Versailles and some other populous places. There is much fruit raised, and some wine, not of the best quality. It breeds many sheep; and of late years the race of the merinos and other fine-woolled sheep has prodigiously increased. There are in many parts manufactures of linen, woollen, and cotton goods, and they are on the increase.

SEISIN, in *Law*, signifies possession. In this sense we say, *premier seisin*, for the first possession. Seisin is divided into that in deed or in fact, and that in law. A seisin in deed is where a possession is actually taken; but a seisin in law is where lands descend, and the party has not entered thereon; or it is where a person has a right to lands, and is by wrong disseised of them. A seisin in law is held to be sufficient to avow on, though to the bringing of an assize, actual seisin is required; and where seisin is alleged, the person pleading it must show of what estate he is seised.

Livery of Seisin, in *Law*, an essential ceremony in the conveyance of landed property, being no other than the pure feudal investiture, or delivery of corporal possession, of the land or tenement. This was held absolutely necessary to complete the donation, *Nam feudam sine investitura nullo modo constitui potuit;* and an estate was then only perfect when, as Fleta expresses it in our law, *fit juris et seisinæ conjunctio.*

Investitures, in their original rise, were probably intended to demonstrate in conquered countries the actual possession of the lord; and that he did not grant a bare litigious right, which the soldier was ill qualified to prosecute, but a peaceable and firm possession. And, at a time when writing was seldom practised, a mere oral gift, at a distance from the spot that was given, was unlikely to be either long or accurately retained in the memory of bystanders, who were very little interested in the grant. Afterwards they were retained as a public and notorious act, that the country might take notice of and testify the transfer of the estate, and that such as claimed title by other means might know against whom to bring their actions.

In all well-governed nations, some notoriety of this kind has ever been held requisite, in order to acquire and ascertain the property of lands. In the Roman law, *plenur*

Seisin.

dominium was not said to subsist unless where a man had both the right and the corporal possession; which possession could not be acquired without both an actual intention to possess, and an actual seisin or entry into the premises, or part of them in the name of the whole. And even in ecclesiastical promotions, where the freehold passes to the person promoted, corporal possession is required at this day to vest the property completely in the new proprietor, who, according to the distinction of the canonist, acquires the *jus ad rem*, or inchoate and imperfect right, by nomination and institution, but not the *jus in re*, or the complete and full right, unless by corporal possession. Therefore in dignities possession is given by instalment, and in rectories and vicarages by induction, without which no temporal rights accrue to the minister, though every ecclesiastical power is vested in him by institution. So also by our law, even in descents of lands, which are cast on the heir by act of the law itself, the heir has not *plenum dominium*, or full and complete ownership, till he has made an actual corporal entry into the lands; for if he dies before entry made, his heir shall not be entitled to take the possession, but the heir of the person who was last actually seised. It is not therefore a mere right to enter, but the actual entry, that makes a man complete owner, so as to transmit the inheritance to his own heirs: *Non jus, sed seisina, facit stipitem.*

Yet the corporal tradition of lands being sometimes inconvenient, a symbolical delivery of possession was in many cases anciently allowed, by transferring something near at hand, in the presence of credible witnesses, which by agreement should serve to represent the very thing designed to be conveyed; and an occupancy of this sign or symbol was permitted as equivalent to an occupancy of the land itself. Among the Jews, we find the evidence of a purchase thus defined in the book of Ruth: "Now this was the manner in former time in Israel, concerning redeeming and concerning changing, for to confirm all things; a man plucked off his shoe, and gave it to his neighbour, and this was a testimony in Israel." Among the ancient Goths and Swedes, contracts for the sale of lands were made in the presence of witnesses, who extended the cloak of the buyer, while the seller cast a clod of the land into it, in order to give possession; and a staff or wand was also delivered from the vender to the vendee, which passed through the hands of the witnesses. With our Saxon ancestors the delivery of a turf was a necessary solemnity in the conveyance of lands; and, to this day, the conveyance of our copyhold estates is usually made from the seller to the lord or his steward by delivery of a rod or verge, and then from the lord to the purchaser by redelivery of the same in the presence of a jury of tenants.

Conveyances in writing were the last and most refined improvement. The mere delivery of possession, either actual or symbolical, depending upon the ocular testimony and remembrance of the witnesses, was liable to be forgotten or misrepresented, and became frequently incapable of proof. Besides, the new occasions and necessities introduced by the advancement of commerce required means to be devised of charging and encumbering estates, and of making them liable to a multitude of conditions and minute designations, for the purposes of raising money, without an absolute sale of the land; and sometimes similar proceedings were found useful in order to make a decent and competent provision for the numerous branches of a family, and for other domestic views; none of which could be effected by a mere simple corporal transfer of the soil from one man to another, which was principally calculated for conveying an absolute and unlimited dominion. Written deeds were therefore introduced, in order to specify and perpetuate the peculiar purposes of the party who conveyed. Yet still, for a very long series of years, they were never made use of, but in company with the more ancient and notorious method of transfer by delivery of corporal possession.

Seistan.

SEISTAN, or Segestan, an extensive country or province, formerly called Nimrose, situated to the east of Persia, betwen Candahar and Khorassan. It is bounded on the north and north-west by Khorassan, on the east by Candahar, and on the south and south-west by Mekran and Kerman. This country, although now reduced to a deplorable condition, once rivalled in prosperity the most flourishing provinces of the empire. It was the country of Jamsheed and Rustum, the heroes of the Shah Nameh, and of Jacob Ben Leth, the conqueror of the caliph of Bagdad. The greater part of the country is flat, sandy, and uninhabited. This is partly occasioned by the wind, which blows during the hot months with such violence as to overwhelm with clouds of sand, houses, gardens, and fields. Captain Christie, who passed through the heart of Seistan in 1810, in his route from Kelat, in Beloochistan, to Herat, says, that from Nooshky to the banks of the Heermund, the country through which he travelled was little better than a desert, intersected by sand-hills. But he travelled at no time twenty-five miles without meeting water. He did not see a single town, or even a village, in the way; and the only inhabitants of this solitary wild that he saw were a few Belooche and Patan shepherds, who lived in tents pitched in the vicinity of the springs. The country through which he passed was covered with an astonishing number of ruined towns, villages, and forts, and at one of these, Kulcauput, was a noble palace, in a tolerable state of preservation; also the ruined remains of a city, which he describes as of great extent. He also met with the ruins of another large city; and a few miles beyond it, the remains of a third. Everywhere he thus saw the traces of ruin and desolation, the fatal consequences of commotion and war. The only remnants of fertility that he met with were near the banks of the noble river Heermund, the ancient Etymander, which flows through the centre of the country, from the mountains of Huzara, beyond Caubul, to the Lake of Zerreh, which is said to be thirty furlongs in length and six in breadth. This river flows through a valley varying in breadth from one to two miles, the desert on one side rising in perpendicular cliffs; the valley, watered by the river, is covered with verdure and brushwood. The capital of the country is Dooshak, where the prince of Seistan resides. It is about eight or nine miles from the Heermund or Helmund. The modern city is small and compact, but the ruins cover a vast extent of ground. It is populous, has a good bazaar, and the inhabitants, who are dressed in the Persian manner, had a more civilized appearance than the other natives of Seistan, who are either Patan or Belooche shepherds, that lead a wandering life, and pitch their tents amidst the ruins of ancient palaces. The country in the vicinity of the capital is open, well cultivated, and produces wheat and barley in sufficient quantities to be exported to Herat. The pasturage is also good and abundant. Colonel Kinneir supposes Dooshak to be no other than the Zaranga of Ptolemy, and that the old name has been lost in the constant revolutions to which the country has been exposed for more than a century, and to which its present desolate state may in a great measure be attributed. Between this city and Ferrah, Captain Christie, to whom we owe the knowledge that we possess of this region, found the country in general desert, except in the immediate neighbourhood of the towns and villages through which he passed. Seistan is at present divided into a number of small independent states, governed by chiefs, who live in fortified villages, situated principally on the banks of the Heermund. The country to the west of this river consists of an arid waste, intersected by one or two ranges of mountains, in the midst of which, about ten days' journey

Seize || Selden.

from Dooshak, lies the city of Kubbees, about fifteen days' march from Kerman and sixteen from Yezd. Couriers travel this desert from Kerman to Herat in eighteen days; but the risk of perishing is so great, that a courier demanded two hundred rupees from Mr Pottinger to carry a letter to Captain Christie. Seistan is now entirely independent of Persia, and is ruled by one of its own chiefs, who cannot raise a revenue of above 80,000 rupees, nor bring more than 3000 troops into the field.

SEIZE, in nautical language, is to make fast or bind, particularly to fasten two ropes together with rope-yarn. The seizing of a boat is a rope tied to a ring or little chain in the fore-ship of the boat, by which means it is fastened to the side of the ship.

SEIZURE, in commerce, an arrest of some merchandise, moveable, or other matter, either in consequence of some law, or some express order of the sovereign. Contraband goods, those fraudulently entered, or landed without entering at all, or at wrong places, are subject to seizure.

SEJANT, a term used in heraldry, when a lion or other beast is drawn in an escutcheon sitting like a cat with his fore-feet straight.

SEJANUS, Ælius, a native of Vulsinum, in Tuscany, who distinguished himself in the court of Tiberius, against whom he formed a conspiracy, and was by the senate condemned to death, and strangled.

SEJUR, a small river of Syria, which rises a little to the north of Antakia, and, after a course of about thirty miles, loses itself in the ground. It is also the name of a small town in Syria, fifteen miles south of Antakia.

SELAME, a cluster of small islands near the coast of Arabia, of which Selame is the chief, at the entrance of the Persian Gulf, near Cape Mussendoon.

SELANG, an island in the Eastern Seas, of inconsiderable size, flat and low. It lies off the southern coast of the island of Batchian, one of the Moluccas. The straits which it forms with this island are narrow, and not five feet in depth. The island forms two harbours with the mainland. Long. 124. 10. E. Lat. 0. 50. S.

SELBISTAN, a town of Persia, in the eastern part of the province of Fars, in a well-peopled and cultivated country, bordering on Kerman.

SELBY, a town of the wapentake of Barton Ash, in the west riding of the county of York, 178 miles from London. It is situated in a level country on the banks of the Ouse, and having a canal which unites that river with the Aire and Calder, has a considerable trade carried on by inland navigation. It has a fine bridge over the Ouse, constructed so as not to impede the vessels. There are some establishments for building large trading ships. The church is a conventual edifice, formerly belonging to the Benedictine monks. There is a good market, which is held on Wednesdays. The population in 1821 amounted to 4097, and in 1831 to 4600.

SELDEN, John, called by Grotius "the glory of England," was born at Salvington, in Sussex, in the year 1584. He was educated at the free school at Chichester, whence he was sent to Hart Hall, in the university of Oxford, where he staid four years. In 1612, he entered himself at Clifford's Inn, in order to study the law; and about two years afterwards removed to the Inner Temple, where he soon acquired great reputation by his learning. He had already published several of his works; and this year he wrote verses in Latin, in Greek, and in English. In 1614, he published his Titles of Honour; and in 1616 his Notes on Sir John Fortescue's book, *De Laudibus Legum Angliæ.* In 1618, he published his History of Tythes, which gave great offence to the clergy, and was animadverted upon by several writers; and for this book he was called before the High Commission Court, and obliged to make a public acknowledgment of his sorrow for having published it. In 1621, being sent for by the parliament, though he was not then a member of that house, and giving his opinion very strongly in favour of their privileges, in opposition to the court, he was committed to the custody of the sheriff of London, but was set at liberty after five weeks' confinement. In 1623, he was chosen burgess for Lancaster; but amidst all the divisions of the nation, he kept himself neutral, prosecuting his studies with such application, that though he was the next year chosen reader of Lyon's Inn, he refused to perform that office. In 1625, he was chosen burgess for Great Bedwin, in Wiltshire, to serve in the first parliament of Charles I., in which he declared himself warmly against the Duke of Buckingham; and on his Grace's being impeached by the House of Commons, he was appointed one of the managers of the articles against him. In 1627 and 1628, he opposed the court party with great vigour. The parliament being prorogued to the 20th of January 1629, Mr Selden retired to the Earl of Kent's house at Wrest, in Bedfordshire, where he finished his *Marmora Arundeliana.* The parliament being met, he, among others, again distinguished himself by his zeal against the court; when the king dissolving the parliament, ordered several of the members to be brought before the King's Bench bar, and committed to the Tower. Among these was Mr Selden, who insisting on the benefit of the laws, and refusing to make his submission, was removed to the King's Bench prison. Being here in danger of his life on account of the plague then raging in Southwark, he petitioned the lord high treasurer, at the end of Trinity term, to intercede with his majesty that he might be removed to the Gate-house, Westminster, which was granted. But in Michaelmas term following, the judges objecting to the lord treasurer's warrant, by which he had been removed to the Gate-house, an order was made for conveying him back to the King's Bench, whence he was released in the latter end of the same year; but fifteen years afterwards the parliament ordered him five thousand pounds for the losses he had sustained on this occasion. He was afterwards committed, with several other gentlemen, for dispersing a libel; but the author, who was abroad, being discovered, they were at length set at liberty. In 1634, a dispute having arisen between the English and Dutch concerning the herring-fishery on the British coast, he was prevailed upon by Archbishop Laud to draw up his *Mare Clausum,* in answer to Grotius's *Mare Liberum;* which greatly recommended him to the favour of the court. In 1640, he was chosen member for the university of Oxford; when he again opposed the court, though he might, by compliance, have raised himself to very considerable posts. In 1643, he was appointed one of the lay members to sit in the assembly of divines at Westminster, and was the same year appointed keeper of the records in the Tower. Whilst he attended his duty in the assembly, a warm debate arose respecting the distance of Jericho from Jerusalem. The party which contended for the shortest distance urged, as a proof of their opinion being well founded, that fishes were carried from the one city to the other, and sold in the market. Their adversaries were ready to yield to the force of this conclusive argument, when Selden, who despised both parties, as well as the frivolousness of their dispute, exclaimed, "Perhaps the fishes were salted." This unexpected remark left the victory doubtful, and renewed the debate; and our author, who was sick of such trifling, soon found employment more suited to his genius; for, in the year 1645, he was made one of the commissioners of the admiralty. The same year he was unanimously elected master of Trinity College, Cambridge, but declined accepting. He died in 1654, and was interred in the Temple-church, where a monument is erected to his memory. Dr Wilkes observes, that he was a man of uncommon gravity and greatness of soul, averse to flattery, liberal to scholars, charitable to the poor; and though he had great latitude in his principles with regard to ecclesiastical

siastical power, yet he had a sincere regard for the Church of England. He wrote many learned works besides those already mentioned, the principal of which are, 1. De Jure Naturali et Gentium, juxta Disciplinam Hebræorum; 2. De Nuptiis et Divorciis; 3. De Anno Civili veterum Hebræorum; 4. De Nummis; 5. De Diis Syris; 6. Uxor Hebraica; 7. Jani Anglorum Facies altera. All his works were printed together in 1726, in three vols. folio.

SELEFKEH, the ancient Calicadnus, in Asia Minor, in the province of Caramania, situated near the mouth of a river called Ghiuk Sooyoo. The modern town is merely an assemblage of mud and wooden huts; it is, however, the residence of an aga under the governor of Cyprus. It is on the site of the ancient Seleucia, the remains of which are still to be seen scattered over a large extent of ground on the western side of the river. Here are found the remains of a theatre, with porticos in front, and other large buildings. Farther on is a temple which had been converted into a Christian church, and several large Corinthian columns about four feet in diameter, a few of which are still standing. A little farther to the southward, near a marble quarry, which seems to have supplied materials for the town, is seen an extensive cemetery, containing sarcophagi of coarse workmanship; and also catacombs, which have been all opened and emptied. On all these remains are inscriptions denoting their origin and object. Near the catacombs is an enormous reservoir hewn out of the soft stone, one hundred and fifty feet by seventy-five, and thirty-five feet in depth. To the west of the town are seen the remains of a citadel. Long. 33. 35. E. Lat. 36. 20. N.

SELENGA, a large river of Siberia, in the southern part of the government of Irkoutsk, which rises beyond the frontier, in the country of the Mongols, where its stream is increased by the accession of the Kharatale and the Iga. It becomes navigable as it approaches the frontiers of the empire, and, flowing from south-east to north-west, it falls by three mouths into Lake Baikal. On its banks are several considerable Russian towns, namely, Verschnei, Oudinsk, Selenginsk, and Kiachta, the great point of commercial intercourse with China.

SELENGINSK, a town of Asiatic Russia, in the government of Irkoutsk, situated on the right bank of the Selenga, in a country consisting chiefly of naked and sandy mountains; and it is ten miles farther down the river before any lands are found fit for the purposes of agriculture. In 1566 a wooden fort or ostrog was built on this spot, which was afterwards converted into a regular fortress, and gave rise to the town, which now contains three churches and a hundred and fifty houses. It is supported, notwithstanding its dreary situation, by being the great thoroughfare of the China trade through Kiachta. Rhubarb is imported in large quantities from the adjacent country of Mongolia. Long. 107. 3. E. Lat. 51. 6. N.

SELENOGRAPHY, a branch of cosmography, which describes the moon, and all the parts and appearances thereof, as geography does those of the earth.

SELEUCIA, in *Ancient Geography*, surnamed *Babylonia*, because situated on its confines, at the confluence of the Euphrates and the Tigris. Ptolemy places it in Mesopotamia. It is called also *Seleucia ad Tigrim*, being washed on the south by the Euphrates, and on the east by the Tigris. It is generally believed to have been built or enlarged by Seleucus Nicanor, master of the east after Alexander by means of which Babylon came to be deserted. It is said to have been originally called *Coche*, though others, as Arrian, distinguish it, as a village, from *Seleucia;* and, according to Zosimus, the ancient name of Seleucia was *Zochasia.* It is now called Bagdad. Long. 44. 21. E. Lat. 33. 10. N. There were many other cities of the same name, all built by Seleucus Nicanor.

SELEUCIDÆ, in *Chronology*. The era of the Seleucidæ, or the Syro-Macedonian era, is a computation of time, commencing from the establishment of the Seleucidæ, a race of Greek kings, who reigned as successors of Alexander the Great in Syria, as the Ptolemies did in Egypt. This era we find expressed in the books of the Maccabees, and on a great number of Greek medals struck by the cities of Syria. The Rabbin call it the *era of contracts*, and the Arabs *therik dilkarnain*, or the era of the two horns. According to the best accounts, the first year of this era falls in the year 311 before Christ, being twelve years after Alexander's death.

SELF-DEFENCE implies not only the preservation of one's life, but also the protection of one's property, because without property life cannot be preserved in a civilized nation. The extent of property essential to life is indeed small and this consideration may enable us to decide a question which some moralists have made intricate. By what means, it has been asked, may a man protect his property? May he kill the person who attacks it, if he cannot otherwise repel the attack?

That a man, in a state of nature, may kill the person who makes an attack on his life, if he cannot otherwise repel the attack, is a truth which has never been controverted; and he may do the same in civil society, if his danger be so imminent that it cannot be averted by the interposition of the protection provided for individuals by the state. In all possible situations, except the three following, whatever is absolutely necessary to the preservation of life may be lawfully performed; for the law of self-preservation is the first and most sacred of those laws which are impressed on every mind by the Author of nature.

The three excepted situations are those of a soldier in the day of battle, of a criminal about to suffer by the laws of his country, and of a man called upon to renounce his religion. The soldier hazards his life in the most honourable of all causes, and cannot betray his trust, or play the coward, without incurring a high degree of moral turpitude. He knows that the very profession in which he is engaged necessarily subjects him to danger; and he voluntarily incurs that danger for the good of his country, which, with great propriety, annexes to his profession peculiar privileges and much glory. The criminal under sentence of death cannot, without adding to his guilt, resist the execution of that sentence; for the power of inflicting punishment is essential to society, and society is the ordinance of God. The man who is called upon to renounce his religion ought to submit to the most cruel death rather than comply with that request, since religion is his only security for future and permanent happiness. But in every other situation, that which is absolutely necessary to the preservation of life is undoubtedly lawful. Hence it is that a person sinking in water is never thought to be guilty of any crime, though he drag his neighbour after him by his endeavours to save himself; and hence, too, a man in danger of perishing by shipwreck may drive another from a plank which cannot carry both of them, for since one of two lives must be lost, no law, human or divine, calls upon either of them to prefer his neighbour's life to his own.

But though the rights of self-defence authorize us to repel every attack made upon our life, and in case of extremity to save ourselves at the expense of the life of our innocent neighbour, it is not so evident that, rather than give to an unjust demand a few shillings or pounds, we may lawfully deprive a fellow-creature of life, and the public of a citizen. A few pounds lost may be easily regained; but life when lost can never be recovered. If these pounds, indeed, be the whole of a man's property; if they include his clothes, his food, and the house where he shelters his head; there cannot be a doubt that, rather than part with them, he may lawfully kill the aggressor, for no man can exist without shelter, and food, and raiment. But it is seldom that an attempt is made, or is indeed practicable, to rob a man at once of all that he possesses. The question, then, of any importance is, may a man put a robber to death rather than part with a small portion of his property? Paley doubts whether he could innocently do so in a state of nature, "because it cannot be contended to be for the augmentation of human happiness, that one should lose his life or limb, rather than another a pennyworth of his property." He allows, that in civil society the life of the aggressor may always be taken away by the person aggrieved, or meant to be aggrieved, when the crime attempted is such as would subject its perpetrator to death by the laws of his country.

To us, however, he seems to lose sight of his own principles. No legislature can have a right to take away life in civil society, but in such cases as individuals have the same right in a state of nature. If therefore a man in the state of nature have not a right to protect his property by killing the aggressor, when it cannot be otherwise protected, it appears to us self-evident that no legislature can have a right to inflict the punishment of death upon such offences; but if the laws inflicting death upon the crime of robbery be morally evil, it is certain that an individual cannot be innocent when he prevents robbery by the death of the robber, merely because he knows that the laws of his country have decreed that punishment against those convicted of the crime. But we think that the protection of property by the death of the aggressor may be completely vindicated upon much more general principles. It is necessary in every state, that property be protected, or mankind could not subsist; but in a state of nature every man must be the defender of his own property, which in that state must necessarily be small; and if he be not allowed to defend it by every means in his power, he will not long be able to protect it at all. By giving him such liberty, a few individuals may, indeed, occasionally lose their lives and limbs for the preservation of a very small portion of private property; but we believe that the sum of human happiness will be more augmented by cutting off such worthless wretches than by exposing property to perpetual depredation; and therefore, if general utility be the criterion of moral good, we must be of opinion that a man may in every case lawfully kill a robber rather than comply with his unjust demand.

But if a man may without guilt preserve his property by the death of the aggressor, when it cannot be preserved by any other means, much more may a woman have recourse to the last extremity to protect her chastity from forcible violation. This, indeed, is admitted by Paley himself, and will be controverted by no man who reflects on the importance of the female character, and the probable consequences of the smallest deviation from the established laws of female honour.

Self-Love is that instinctive principle which impels every animal, rational and irrational, to preserve its life and promote its own happiness. It is very generally confounded with selfishness; but we think that the one propensity is distinct from the other. Every man loves himself, but every man is not selfish. The selfish man grasps at all immediate advantages, regardless of the consequences which his conduct may have upon his neighbour. Self-love only prompts him who is actuated by it to procure to himself the greatest possible sum of happiness during the whole of his existence. In this pursuit the rational self-lover will often forego a present enjoyment to obtain a greater and more permanent one in reversion; and he will as often submit to a present pain to avoid a greater one hereafter. Self-love, as distinguished from selfishness, always comprehends the whole of a man's existence, and in that extended sense of the phrase, we hesitate not to say that every man is a self-lover; for, with eternity in his view, it is surely not possible for the most disinterested of the human race not to prefer himself to all other men, if their future and everlasting interests could come into competition. This indeed they can never do; for though the introduction of evil into the world, and the different ranks which it makes necessary in society, put it in the power of a man to raise himself, in the present state, by the depression of his neighbour or by the practice of injustice, yet in the pursuit of a prize which is to be gained only by soberness, righteousness, and piety, there can be no rivalship among the different competitors. The success of one is no injury to another; and, therefore, in this sense of the phrase, self-love is not only lawful, but absolutely unavoidable. It has been a question in morals, whether it be not likewise the incentive to every action, however virtuous or apparently disinterested?

Those who maintain the affirmative side of this question say, that the prospect of immediate pleasure, or the dread of immediate pain, is the only apparent motive to action in the minds of infants, and indeed of all who look not before them, and infer the future from the past. They own, that when a boy has had some experience, and is capable of making comparisons, he will often decline an immediate enjoyment which he has formerly found productive of future evil more than equivalent to all its good; but in doing so they think, and justly, that he is still actuated by the principle of self-love, pursuing the greatest good of which he knows himself to be capable. After experiencing that truth, equity, and benevolence in all his dealings is the readiest, and indeed the only certain method of securing to himself the kindness and good offices of his fellow-creatures, and much more when he has learned that they will recommend him to the Supreme Being, upon whom depend his existence and all his enjoyments, they admit that he will practise truth, equity, and benevolence, but still, from the same principle, pursuing his own ultimate happiness as the object which he has always in view. The prospect of this great object will make him feel an exquisite pleasure in the performance of the actions which he conceives as necessary to its attainment, until at last, without attending in each instance to their consequences, he will, by the great associating principle which has been elsewhere explained, feel a refined enjoyment in the actions themselves, and perform them, as occasions offer, without deliberation or reflection. Such, they think, is the origin of benevolence itself, and indeed of every virtue.

Those who take the other side of the question can hardly deny that self-love thus modified may prompt to virtuous and apparently disinterested conduct; but they think it degrading the dignity of a man to suppose him actuated solely by motives which can be traced back to a desire of his own happiness. They observe, that the Author of our nature has not left the preservation of the individual, or the continuance of the species, to the deductions of our reason, computing the sum of happiness which the actions necessary to these ends produce to ourselves. On the contrary, he has taken care of both, by the surer impulse of instinct planted in us for these very purposes. And is it conceivable, say they, that he would leave the care of our fellow-creatures a matter of indifference, until each man should be able to discover or be taught that by loving his neighbour, and doing him all the good in his power, he would be most effectually promoting his own happiness? It is dishonouring virtue, they continue, to make it proceed in any instance from a prospect of happiness or a dread of misery; and they appeal from theory to fact, as exhibited in the conduct of savage tribes, who deliberate little on the consequences of their actions.

Their antagonists reply, that the conduct of savage tribes is to be considered as that of children in civilized nations, regulated entirely by the examples which they have before eligenstadt || elkirk.

them; that their actions cannot be the offspring of innate instincts, otherwise savage virtues would, under similar circumstances, be everywhere the same, which is contrary to fact; that virtue proceeds from an interested motive on either supposition; and that the motive which the instinctive scheme holds up is the more selfish of the two. The other theory supposes, that the governing motive is the hope of future happiness and the dread of future misery; the instinctive scheme supplies a present motive in the self-complacency arising in the heart from a consciousness of right conduct. The former is a rational motive; the latter has nothing more to do with reason than the enjoyment arising from eating or drinking, or from the intercourse between the sexes. See Metaphysics and Moral Philosophy.

SELIGENSTADT, a city of the grand duchy of Hesse-Darmstadt, in Germany, in the province of Starkenburg, and the capital of a bailiwick of the same name. It stands on the river Maine, is surrounded with walls, and contains an ancient monastery, 420 houses, and 2640 inhabitants.

SELINO, a town of the island of Candia, in the Levant. It is the capital of a circle of its own name, situated at the south-west point of that island, with good anchorage in the road, which is defended by a fort.

SELINGAN, a small island in the Sooloo Archipelago. Long. 118. 15. E. Lat. 6. 4. N.

SELINTY, a bold and romantic headland in Caramania, situated on the ruins of the ancient Trajanopolis. On the highest point are the ruins of a castle, which commands the ascent of the hills in every direction.

SELKIRK, Alexander, whose adventures gave rise to Defoe's well-known historical romance of Robinson Crusoe, was born at Largo, in Fifeshire, Scotland, about the year 1676. He was bred a seaman, and went from England in 1703, in the capacity of sailing-master of a small vessel called the Cinque-Ports galley, Charles Pickering captain. In September the same year he sailed from Cork, in company with another ship called the St George, commanded by the celebrated navigator William Dampier, intended to cruise against the Spaniards in the South Sea. On the coast of Brazil, Pickering died, and was succeeded in the command by his lieutenant Thomas Stradling. They proceeded on their voyage round Cape Horn to the island of Juan Fernandez, whence they were driven by the appearance of two French ships of thirty-six guns each, and left five of Stradling's men there on shore, who were taken off by the French. From this they sailed to the coast of America, where Dampier and Stradling quarrelled, and separated by agreement, on the 19th of May 1704. In September following, Stradling came again to the island of Juan Fernandez, where Selkirk and his captain had a difference, which, with the circumstance of the ship's being very leaky, and in bad condition, induced him to determine upon staying there alone; but when his companions were about to depart, his resolution was shaken, and he desired to be taken on board again. The captain, however, refused to admit him, and he was obliged to remain, having nothing but his clothes, bedding, a gun, and a small quantity of powder and ball; a hatchet, a knife, and a kettle; with his books, and mathematical and nautical instruments. He kept up his spirits tolerably till he saw the vessel put off, when, as he afterwards related, his heart yearned within him, and melted at parting at once with his comrades and all human society.

Thus left sole monarch of the island, with plenty of the necessaries of life, he found himself in a situation which was hardly supportable. He had fish, goats' flesh, turnips and other vegetables; yet he grew dejected, languid, and melancholy, to such a degree, as to be scarcely able to refrain from doing violence to himself. Eighteen months passed before he could, by reasoning, reading his Bible, and study, be thoroughly reconciled to his condition. At length he grew happy, employing himself in decorating his huts, chasing the goats, whom he equalled in speed, and scarcely ever failed in catching. He also tamed young kids, laming them to prevent their becoming wild; and he kept a guard of tame cats about him, to defend him when asleep from the rats, that were very troublesome. When his clothes were worn out, he made others of goat-skins, but could not succeed in making shoes, with the use of which, however, habit, in time, enabled him to dispense. His only liquor was water. He computed that during his abode in the island he had caught a thousand goats, of which he had let go five hundred, after marking them by slitting their ears. Commodore Anson's people, who were there about thirty years afterwards, found the first goat which they shot upon landing was thus marked, and, as it appeared to be very old, concluded that it had been under the power of Selkirk. But it appears by Captain Carteret's account of his voyage in the Swallow sloop, that other persons practised this mode of marking, as he found a goat with his ears thus slit on the neighbouring island of Mas-a-fuera, where Selkirk never was. He made companions of his tame goats and cats, often dancing and singing with them. Although he constantly performed his devotions at stated hours, and read aloud, yet, when he was taken off the island, his language, from disuse of conversation, had become scarcely intelligible. In this solitude he continued four years and four months, during which time only two incidents happened which he thought worth relating, the occurrences of every day being in his circumstances nearly similar. The one was, that, pursuing a goat eagerly, he caught it just on the edge of a precipice, which was covered with bushes, so that he did not perceive it; and he fell to the bottom, where he lay, according to Captain Rogers's account, twenty-four hours senseless; but, as he related to Sir Richard Steele, he computed, by the alteration of the moon, that he had lain three days. When he came to himself, he found the goat lying under him dead. It was with great difficulty that he could crawl to his habitation, whence he was unable to stir for ten days, and did not recover of his bruises for a long time. The other event was the arrival of a ship, which he at first supposed to be French. And such is the natural love of society in the human mind, that he was eager to abandon his solitary felicity, and surrender himself to them, although enemies; but upon their landing he found them to be Spaniards, of whom he had too great a dread to trust himself in their hands. They were by this time so near that it required all his agility to escape, which he effected by climbing into a thick tree, being shot at several times as he ran off. Fortunately the Spaniards did not discover him, though they stayed some time under the tree where he was hidden, and killed some goats just by. In this solitude Selkirk remained until the 2d of February 1709, when he saw two ships come into the bay, and knew them to be English. He immediately lighted a fire as a signal; and on their coming on shore, found they were the Duke, Captain Rogers, and the Duchess, Captain Courtney, being two privateers from Bristol. He gave them the best entertainment he could afford; and as they had been a long time at sea without fresh provisions, the goats which he caught were highly acceptable. His habitation, consisting of two huts, one to sleep in, and the other for dressing his food, was so obscurely situated, and so difficult of access, that only one of the ship's officers would accompany him to it. Dampier, who was pilot on board the Duke, and knew Selkirk very well, told Captain Rogers that, when on board the Cinque-Ports, he was the best seaman in the vessel, upon which Captain Rogers appointed him master's mate of the Duke. After a fortnight's stay at Juan Fernandez, the ships proceeded on their cruize against the Spaniards; plundered a town on the coast of Peru; took a Manilla ship off Califor-

Selkirk.

nia; and returned by way of the East Indies to England, where they arrived on the 1st of October 1711; Selkirk having been absent, on the day of his arrival in London, eight years one month and three days, more than half of which time he had spent alone on the island. The public curiosity being excited respecting him, he was induced to put his papers into the hands of Defoe, to arrange and form them into a regular narrative. These papers must have been drawn up after he left Juan Fernandez, as he had no means of recording his transactions there. Captain Cooke remarks, as an extraordinary circumstance, that he had contrived to keep an account of the days of the week and the month; but this might be done, as Defoe makes Robinson Crusoe do, by cutting notches in a post, or many other methods. From this account of Selkirk, Defoe adopted the notion of writing a more extensive work, the romance of Robinson Crusoe, and very dishonestly defrauded the original proprietor of his share of the profits. After his return to England he waited in London till he got his effects realized, and then proceeded, in the spring of 1712, to his native village Largo. For a few days he enjoyed the society of his relatives and friends; but, from long habit, he soon felt averse to society, and was most happy in being alone. In the upper part of the garden attached to his father's house, he formed a kind of cave or grotto, which commanded an extensive and delightful view of the bay of Largo, and the shores of the Forth. In musing here, or wandering through a secluded and solitary valley called Keil's Den, and fishing in the bay, he spent the greater part of his time. How long he remained here cannot be ascertained, but he eloped some time afterwards with a girl of the neighbourhood, named Sophia Bruce, and proceeded with her to London. He never returned to Largo, and but little is known of him during the latter part of his life. Sophia Bruce appears to have died between 1717 and 1720; for in the latter year he again married Frances Candis, who survived him. Selkirk died lieutenant on board his majesty's ship Weymouth, some time in the year 1723; and it is believed that he had no children by either of his wives.[1]

Selkirk, an ancient royal burgh, and chief town of the county of Selkirk, in Scotland. It is situated on an elevation overlooking the valley of the river Ettrick, and commands an extensive view. It consists chiefly of one street, which expands at the market-place into an open space; and in it is the ancient tolbooth. In addition to this main street, there are a few small streets that diverge from it. The town has not increased in size or in importance for centuries; but it has been much improved of late years, and now contains many good houses, with a town-hall, having an elegant spire 110 feet in height, and in which there are apartments for the burgh and sheriff courts. There are two places of worship, one belonging to the established church, and the other to the United Associate Synod. A new prison has been erected at the north side of the town; and it also possesses several excellent schools, in which the classics, French, Italian, and the more usual branches, are taught.

Selkirk was formerly famed for the manufacture of shoes, in which it had an extensive trade; but it has now no manufactures of any consequence, the restrictions on trade, and the jealousy of the burghers or freemen, preventing young men of small capital from pushing business, and forcing them to repair to places more open to enterprise. The property of the burgh extends to 1784 acres, and its yearly income amounts to nearly L.1100. In 1833, its debts amounted to L.16,088. It is governed by a provost, two bailies, a treasurer, and twenty-nine councillors; and it votes with the county in returning a member to parliament. The population of the burgh and parish in 1821 amounted to 2728, and in 1831 to 2833. The population of the burgh alone in the latter year was 1880.

During the wars between England and Scotland the citizens of Selkirk were famed for their courage. A party of them, amounting to between eighty and a hundred, under the command of the town-clerk, William Brydone, proceeded to the battle of Flodden, and fought with such gallantry that only a few returned. Brydone was afterwards knighted for his conduct; and the town received from James V. a grant of a thousand acres, as a recompense for the courage of the burghers, and for the town being totally burned by the English, in revenge for the bravery displayed by them at that battle. Brydone's sword is still in the possession of his lineal descendants; and a pennon, taken, it is believed, from the Percys, by a person of the name of Fletcher, is still kept by the successive deacons of the weavers, and displayed on all civic occasions by that corporation. A mile north from the town is Philiphaugh, where the celebrated Marquis of Montrose was defeated by the covenanters under General Leslie.

SELKIRKSHIRE, a county of Scotland, situated between 55° 21′ and 55° 42′ north latitude, and between 2° 48′ and 3° 20′ west longitude from Greenwich. It has Mid-Lothian, or the county of Edinburgh, on the north; Roxburghshire on the east and south-east; Dumfriesshire on the south; and Peeblesshire, or Tweeddale, on the west; the line which separates it from these counties being on all sides, but especially the south, exceedingly irregular. Its area has been computed very differently; but, according to the latest authorities, it appears that its extreme length is thirty miles, its extreme breadth twenty, and it is calculated to contain 264½ square miles, nearly equal to 169,280 English acres. It includes only two entire parishes, Yarrow and Ettrick; the parishes of Selkirk and Galashiels being partly in Roxburghshire. These may be said to form the county, although small parts of the parishes of Ashkirk, Innerleithen, Peebles, Roberton, and Stow, are also included in it.

This is almost entirely a pastoral district, and in many respects bears a resemblance to the higher parts of the contiguous county of Roxburgh. Like the latter county, the general declivity of the mountain range is from west-south-west to east-north-east, and all its streams discharge themselves into the Tweed. The rocks are of the transition series, and are chiefly graywacke, graywacke-slate, and clay-slate. On the borders of Peeblesshire extensive layers of porphyry, alternating with thin strata of slate and granite, are to be found. The hills are generally ridge-shaped, and rounded on the tops, with acclivities of from 10° to 30°. The secondary valleys are small, being caused by the Ettrick and Yarrow running nearly parallel, and at no very great distance from each other; but where the Yarrow and Tweed diverge, the valleys increase in magnitude, as they are then drained by larger streams. Several of the hills are above 2300 feet in height, such as Windlestraw Law, at the northern extremity of the county, on the confines of Mid-Lothian; Blackhouse Heights (2370); Minehmoor (2280), on the borders of Peeblesshire; and Ettrick-pen (2200), on the south-west boundary. The lower hills are for the most part green, and afford good pasturage for sheep; but heath prevails on many of the higher grounds, especially towards the south-west. The lowest land is 280 feet, and the sites of many of the houses are from 600 to 1000 feet and upwards, above the level of the sea.

The rivers are, the Tweed, which crosses the north side of the county in its course from Peeblesshire on the west to Roxburghshire on the east; the Gala, which for some distance forms the boundary with Roxburghshire on the north-east, and falls into the Tweed, from the north, a little below Galashiels; the Cador, a very beautiful stream, which also joins the Tweed from the north; the Ettrick and Yarrow, which have their sources on the confines of the county of Dumfries, and, flowing north-east almost parallel to each other, join their streams above Selkirk, and afterwards, under the name of Ettrick, passing to the west of that town, and for a short distance along the boundary with Roxburghshire, enter the Tweed, in which their name is lost, and which then becomes the boundary with that county; the Ale, which rises in the north-east, and soon after passes into Roxburghshire; and also the Borthwick, which washes the north-eastern boundary. Next to the Tweed, the most considerable waters are the Ettrick and the Yarrow, which receive, in the first instance, nearly all the other streams that traverse this district. Both have been celebrated in song, and have given their names to some plaintive melodies of great beauty and feeling. The scenery on the Yarrow is exceedingly romantic and delightful. Soon after its rise, it passes through two lakes, the Loch of the Lows, and St Mary's Loch; the latter, which is separated from the former only by a narrow neck of level ground, and is three miles long, having its banks partly covered with coppice-wood, is the finest piece of water in the south of Scotland. From thence the Yarrow flows for eight or nine miles, through sheep-walks, without wood or cultivation; but afterwards the sides of the lofty hills in its course are covered with wood to a considerable height, and its valley is embellished with a variety of bushes and wild flowers. Ettrick, the larger stream, has a wider and more cultivated valley; and a little before it receives the Yarrow, natural wood begins to appear on its banks. It afterwards flows for four miles through a rich tract, sheltered by plantations on the hills, till it loses its name in the Tweed. From this river the whole district has been sometimes called Ettrick Forest; but the name of Forest here, as elsewhere, has long since ceased to denote the existence of extensive woodlands, of which, whatever may have been the case formerly, scarcely any traces now remain. Besides the two lakes we have mentioned, a great many smaller ones are scattered over the east and south-east quarters, of which the more considerable are Loch Alemoor, the principal source of the Ale, and Loch Oakermoor, noted for the vast quantity of marl which it contains.

---

[1] Life and Adventures of Alexander Selkirk, by John Howell, Edinburgh.

This county is deficient in coal, limestone, and sandstone, and it lies under the same disadvantages as Roxburghshire, from the great distance at which it lies from markets where coal and lime are to be had. It is fortunate, however, that in the lakes and mosses there is a great deal of marl, which serves as excellent manure for the arable land in their vicinity. The arable land lies on an elevation of from 280 to 800 feet, and does not much exceed one twentieth of the whole county. It is light, dry, and easily cultivated; and it produces wheat, oats, barley or bear, turnips, and potatoes. Wheat is regularly grown in the lower parts of the county, and even in the higher it has been raised at the height of 700 feet, yielding a good return; and it may be said that agriculture is as well understood and followed out in this as in any other of the Scotch counties. The rotation in crops is generally on the five-shift system of husbandry; although, near the towns, where land is high and manure can be easily had, the four-shift is too often followed. This has increased the disease of the turnip crop, called fingers-and-toes, and has proved very injurious to the red clover.

The average rent of land is, on the arable farms, from one pound four shillings to three pounds an acre; and on the pastoral farms from two shillings and sixpence to five shillings and sixpence an acre. The grazing of an ox or cow throughout the year is about five pounds. In Ettrick it is from two pounds to two pounds five shillings; and that of a sheep is from four shillings and sixpence to six shillings and sixpence. The wages paid to farm-servants and shepherds are nearly the same as in Roxburghshire. The following summary of the produce and value of the parishes of Selkirk, Galashiels, Yarrow, and Ettrick, as stated in the New Statistical Account of Scotland, will more fully explain the value of the county.

PARISH.	Square Miles in extent.	Acres.					Total yearly Value of Raw Produce raised.		
		Cultivated, or occasionally in Tillage.	Uncultivated.	Capable of being Cultivated with a Profit.	In undivided Common.	Under Wood.			
Selkirk.....	10	3000	2,300	0	0	1000	£10,681	18	0
Galashiels.	15	3000	6,000	0	0	500	10,869	10	6
Yarrow....	111	2740	67,800	260	0	610	28,606	0	0
Ettrick.....	68	217	43,086	163	0	270	12,745	0	0
	204	8957	119,186	423	0	2380	£62,902	8	6

The leases of the farms on the Buccleuch estates are for nine years; but this is almost no drawback, as the occupiers are rarely removed. On other estates the leases run generally for nineteen years.

The rest of the county is almost exclusively occupied by sheep, which are now, for the most part, of the Cheviot breed, though not often pure, and scarcely in any instance equal to those of Roxburghshire. The black-faced or forest breed are better adapted for the greater part of the pasturage than the Cheviots; but their wool is coarse, and not well adapted for manufacture. Yet it is generally allowed, that if proper care were taken to cross the ewes with Cheviot rams, and never allow them to recross, a stock of sheep suitable to the range of pasture, and with improved wool, would soon increase, and take the place of the present breed. The number of sheep usually in pasture amounts to 55,000, of which 3000 or 4000 are of the black-faced, 4000 Leicesters, and the remainder Cheviots. The cows are mostly of the short-horned, or of the Ayrshire breeds. Small farmers and feuars prefer the latter, as being more easily brought up, and affording more milk. Highland stots have been introduced, within these few years, to pasture among the sheep, as it has been found that from the complete draining of the district, the overflow of succulent grasses is such, that without a mixture of cattle with the sheep, the grass is totally lost. The greater number of cattle a farmer keeps on his pasture, according to its extent, from May to the middle of August, the more sheep he is able to feed during winter. The valued rent of the county is L.80,307. 15s. 6d. Scotch, and the real rent of the lands and houses in 1812 was L.41,162. 10s. sterling. The annual value of real property, as assessed in April 1815, was L.43,584. Two fifths of the whole property are held under entail. The principal proprietors are the Duke of Buccleuch, who possesses about one half of the extent, and about one third of the rental; the Earl of Traquair, Lords Elibank and Napier, Johnston of Alva, with fifteen other proprietors, whose lands stand valued in the cess-books from L.1000 to L.2000 Scotch.

Selkirk, the county town, and the town of Galashiels, contain nearly all that part of the population which is not employed in agriculture. A considerable portion of the wool of the county finds a ready market at Galashiels. An inkle-work and some tanneries are the only other branches carried on for sale out of the county; so that its exports consist chiefly of raw produce, of which its sheep and wool are by far the most considerable articles.

(See Douglas' Survey of Selkirkshire; the New Statistical Account of Scotland, No. 1; and the Quarterly Journal of Agriculture, No. 18.)

Selkirkshire returns a member to parliament. The population in 1811, 1821, and 1831, are shown in the following table.

Population of Selkirkshire.

YEARS.	HOUSES.			OCCUPATIONS.			PERSONS.		
	Inhabited.	Families.	Uninhabited.	Families chiefly employed in Agriculture.	Families chiefly employed in Trade, Manufactures, and Handicraft.	All other Families not comprised in the two preceding classes.	Males.	Females.	Total of Persons.
1811	1080	1258	41	500	363	395	2750	3139	5889
1821	1081	1372	36	421	409	542	3205	3432	6637
1831	1094	1391	62	474	450	467	3394	3439	6833

SELLA, a town of Spain, in what is called the kingdom of Valentia, in the province of Alcoy. It is situated on the banks of the river Alcoy, and near to its entrance into the Mediterranean Sea. It contains about 2000 inhabitants, who are chiefly employed in making cordage and fishing-nets from esparto, which grows abundantly in the neighbourhood.

SELMAST, a town of Persia, in the province of Azerbijan, containing about 2000 inhabitants, principally Nestorian Christians. It is famed for its lofty poplars and delightful gardens. It is seventy-five miles west-south-west of Tabreez.

SELTERS, or SELTZERS, a village of the principality of Nassau, in Germany, about ten miles from Coblentz. The name of the mineral spring here is celebrated in every part of Europe. Seltzer water is brought to this country in stone bottles, which are closely corked and sealed, and contain about three pints each; and when they are well secured, it keeps unchanged for a considerable time. Seltzer water, according to the analysis of Bergman, contains, in an English wine pint,

	Grains.
Carbonate of lime	3
Ditto of magnesia	5
Ditto of soda	4
Muriate of soda	17·5
	29·5

The same quantity of water also yields seventeen cubic inches of a gaseous substance, which is found to be almost entirely pure carbonic acid gas. This water has been long in high repute on account of its medicinal virtues, and we have no doubt that it may be used with considerable benefit in many of those complaints which arise from a deranged state of the stomach and bowels. The usual dose of this water is from half a pint to a pint; but in most cases it may be drunk freely. From its agreeable taste, and its exhilarating effects on the spirits, it is extensively employed at table as a common drink in Germany and Holland. In this country also both the real and the artificial Seltzer water is largely used for the same purpose. Seltzer water may be artificially imitated, by adding the ingredients discoverable by analysis, and in the same proportion.

SEMAO, an island in the Eastern Seas, about twenty-four miles in length from north to south, and from six to ten in breadth. A strait, called the Strait of Semao, separates it from the south-west end of the island of Timor. This strait, which has a good depth of water, affords secure shelter to ships during the strength of the westerly monsoons. Long. 123. 45. E. Lat. 10. 15. S.

SEMENDRA, a city in the north-west of Turkey in Europe, the capital of a province of the same name in the ancient Servia. It is built on the western branch of the river Morava, where it falls into the Danube. It is fortified and defended by an ancient castle, and contains the cathedral of a Greek bishop, several mosques, and about 8000 inhabitants, who subsist by trading and fishing on the rivers. Long. 21. 23. E. Lat. 44. 37. N.

SEMENTINÆ FERIÆ, in *Antiquity*, were feasts held annually among the Romans, to obtain of the gods a plentiful harvest. They were celebrated in the temple of Tellus, where solemn sacrifices were offered to Tellus and Ceres. These feasts were held about seed-time, usually in the month of January; for, as Macrobius observes, they were moveable feasts.

SEMI, a word borrowed from the Latin, signifying *half*, but only used in composition with other words.

SEMI-ARIANS, in *Ecclesiastical History*, a branch of the ancient Arians, consisting, according to Epiphanius, of such as, in appearance, condemned the errors of that heresiarch, but yet acquiesced in some of his principles, only palliating and hiding them under softer and more moderate terms. Though they separated from the Arian faction, they could never be brought to acknowledge that the Son was "homoousios," that is, consubstantial, or of the same substance with the Father; they would only allow him to be "homoiousios," that is, of a like substance with the Father, or similar to the Father in his essence, not by nature, but by a peculiar privilege.

The Semi-Arianism of the moderns consists in their maintaining that the Son was from all eternity begotten by the will of the Father, contrary to the doctrine of the orthodox, who seem to teach that eternal generation is necessary. Such, at least, are the respective opinions of Dr Clarke and Bishop Bull.

SEMICIRCLE in *Geometry*, is half a circle, or that figure which is comprehended between the diameter of the circle and half its circumference.

SEMICOLON, in *Grammar*, one of the points or stops used to distinguish the several members of a sentence from each other.

The mark or character of a semicolon is (;), and it has its name from being of somewhat less effect than a colon, or as demanding a shorter pause.

The proper use of the semicolon is to distinguish the conjunct members of a sentence. Now, by a conjunct member of a sentence is meant such a one as contains at least two simple members. Whenever, then, a sentence can be divided into several members of the same degree, which are again divisible into other simple members, the former are to be separated by a semicolon. For instance, "If fortune bear a great sway over him, who has nicely stated and concerted every circumstance of an affair; we must not commit every thing, without reserve, to fortune, lest she should have too great a hold of us."

SEMIDIAMETER, half the diameter, or a right line drawn from the centre of a circle to its circumference; being the same with what is otherwise called the *radius*.

SEMIPALATNOI, a fortress of Asiatic Russia, in the southern part of the government of Tomsk, erected for the purpose of protecting the trade carried on with the Calmucks and Bucharians. It was first built in the year 1718; but, owing to the inundations of the river, it was swept away, and had to be removed successively from one spot to another. The principal fortress forms a square composed of wooden ramparts, and surrounded by a ditch. There are two villages, the one above and the other below, both palisaded, like the fort, and containing above two hundred houses. The trade carried on by the Russians with the Kirghises consists of an exchange of toys and trifles for horses and cattle. It is also frequented by traders from Little Bucharia, who bring chiefly cotton goods of inferior quality. Long. 80. 10. E. Lat. 50. 20. N.

SEMIPELAGIANS, in *Ecclesiastical History*, a name given to such as retain some tincture of Pelagianism. See PELAGIANS.

The doctrines of this sect, as well as those of their predecessors the Pelagians, have their common source in Pelagius, a native of Britain, of whom we have already taken notice. He is said to have been but a simple monk, and not in orders. Having gone to Rome about the end of the fourth century, he lived there for some years with reputation, and was considered as both pious and virtuous. Rufinus, a priest of Aquileia, having come to Rome in the year 397, is affirmed by some to have been the person who suggested to Pelagius his peculiar doctrines.

In the year 400 Pelagius began to teach his opinions at Rome, both by speech and by writing. He was not the only person who taught these doctrines, of which we have elsewhere enumerated the heads. His friend and companion Celestius, an abler man than himself, likewise maintained them, and with much more address and subtilty. After having promulgated them in Rome, they went into Sicily, where they lived for some time; and thence, in the year 411, they passed over into Africa. Pelagius soon afterwards went into Palestine, while Celestius remained at Carthage, and was preparing himself to take the order of priesthood; but it being soon discovered that he taught a new doctrine,[1] he was accused by the deacon Paulinus in a synod held at Carthage in 412, at which Aurelius the bishop presided. Celestius, on being charged by Paulinus with denying original sin, made answer, "that in truth he doubted whether the sin of Adam was transmitted to his posterity." He did not, however, own that children had no need of baptism, although this was one of the Pelagian tenets. On the contrary, he wrote a little discourse, in which he acknowledged that children had need of redemption, and that they could not obtain it without baptism. The bishops at the council of Carthage condemned the doctrines of Celestius, and excommunicated him. From this sentence he appealed to the bishop of Rome; but he neglected to pursue his appeal, and went to Ephesus, where he endeavoured to get himself ordained priest. In the mean time, Pelagius having retired into Palestine, was kindly received by St Jerome's enemy, John of Jerusalem. With him he entered into an engagement to attack the reputation of that author. St Jerome defended himself from their assault, attacking the doctrines of Pelagius,[2] and in this undertaking he was soon assisted by St Augustin. About this time Orosius having gone from Spain into Africa, and thence into Palestine, published there the proceedings against Celestius at Carthage, and was prevailed upon by the bishop of Jerusalem to enter into a conference with Pelagius in his presence; but the bishop having shown too much partiality for Pelagius, Orosius would not acknowledge him as a judge, but demanded that the decision of that affair, which was among the Latins, might be referred to judges who understood the language. This happened in the year 415, at which time there were in Palestine two French prelates, who, being driven from their dioceses, fled into that country, and having been apprised of the opinions of Pelagius and Celestius, drew up an abridgment from their own books, of the errors imputed to them.[3] To this they joined the articles condemned in the synod of Carthage, and some others, which were sent from Sicily by Hilarius to St Augustin, and then presented the abridgment to the bishop of Cæsarea. The matter was referred to a council of fourteen bishops, at which, when the memoir was read, Pelagius explained himself upon some articles, and denied that he was the author of others. He also disowned the propositions condemned at Carthage, and some others ascribed to Celestius. He did not even hesitate to condemn them; upon which the bishops decided, that since Pelagius approved the doctrines of the church, and rejected and condemned what was contrary to its belief, they acknowledged him to be of the ecclesiastical and catholic communion.

Orosius, on his return to Africa, took with him the memoir against Pelagius, and presented it to a meeting of bishops held at Carthage in 416.[4] Having read over what had been done at a former meeting against Celestius, they declared that both he and Pelagius ought to be anathematized if they did not publicly renounce and condemn the errors imputed to them. The bishops of this meeting, and those of Numidia, assembled the same year at Milivetum, wrote upon the subject to Pope Innocent, who approved of the judgment of the African prelates, and declared Pelagius, Celestius, and their followers excommunicated.[5] Innocent gave an account of this judgment to the bishops of the East, and the matter seemed altogether at an end, when he died; but Celestius having been made priest at Ephesus, and having gone to Constantinople, whence he was driven by Atticus, bishop of that city, who also wrote against him to Asia and Africa, he came to Rome in the beginning of the pontificate of Zozimus, and undertook to pursue the appeal which he had formerly made from the judgment of the synod of Carthage. Having cited his accuser Paulinus, and offered to justify himself, he presented a confession of faith, in which he acknowleged that children ought to be baptized, in order to inherit the kingdom of heaven; but he denied that the sin of Adam was transmitted to his children. He appeared before the bishops and clergymen assembled by the pope, and declared that he condemned all the errors with which he had been charged. The pope delayed his judgment for two months, and in the mean time received a letter and a confession of faith from Pelagius, which were very artfully drawn up. When the time for judgment arrived, Zozimus held a synod, and said that he thought the declarations of Pelagius and Celestius sufficient for their justification. He was displeased at the two French bishops for not appearing against them, and wrote two letters on that head, one to the bishops of Africa, and another in particular to Aurelius, bishop of Carthage. The African bishops, to the number of 214, without regarding the judgment passed at Rome, assembled at Carthage, and, having confirmed their former decisions, condemned the doctrines of the Pelagians. They wrote to the bishop of Rome to acquaint him that he had been deceived by Celestius, and discovered to him the equivocations of his letter and the confession of faith of Pelagius, sending him a memoir of the errors of which he should require a distinct and precise revocation from the two heretics. The pope made answer, that although his authority was so great that none durst dissent from his judgment, still that he was willing to communicate the matter

Semipelagians.

to them, and would let it remain in the same state, until a new deliberation could take place. This letter was presented to a council held at Carthage in 418, at which eight canons were drawn up against the Pelagian heresy. The bishop of Rome, in the mean time, was inclined to examine again the affair of Celestius, and to endeavour to draw from him distinct and precise answers according to the plan suggested by the African bishops in their memoir; but Celestius would not come forward, and accordingly withdrew from Rome. From his flight the pope concluded that he had formerly imposed upon him, and that he held the new doctrines; and, accordingly, changing his opinion with respect to him, he approved of the decrees of the African prelates, and renewed the condemnations of his predecessor, Pope Innocent, against him and Pelagius.[1] This judgment he published in a letter which was sent to all the bishops. About the same time an edict was published by the Emperor Honorius against Pelagius and Celestius, ordering that they should be banished from Rome, and that all their followers should be sent into exile.

In the following year Honorius published another edict, by which it was ordered, that the bishops who would not sign the pope's letter should be deprived of their churches. Accordingly, Julian the bishop of Eclana, who was afterwards head of the party, and seventeen other bishops, were cashiered; upon which they wrote a letter to Rufus, bishop of Thessalonica, and demanded a universal council from the emperor, which was refused. Celestius returned again to Rome, but was again expelled from the city; whilst his followers, being expelled from Italy, retired to different countries. Some of them came over into Britain, and others went into the East. Atticus banished them from Constantinople, and they were also banished from Ephesus. Theodotus, bishop of Antioch, condemned them in a synod held at Diospolis, and banished Pelagius and his followers out of Palestine, whither they had returned. Julian, the bishop, was condemned in a provincial synod of Cilicia, whither he had retired to Theodorus, bishop of Mopsuesta, who was obliged to anathematize him. What became of Pelagius is unknown, as history gives no further account of him; but Celestius having returned to Rome, and being driven from thence by Pope Celestin, went with Julian and some other bishops of their party to Constantinople, where they endeavoured to prevail upon the Emperor Theodosius to assemble a council, instead of which he ordered them to leave the city. After this they joined with the Nestorians,[2] and were condemned together with them in a general council held at Ephesus in 431; and there now remained but a small number of Pelagians dispersed in the West. Julian, after having endeavoured several times to get himself reinstated in his bishopric, was at last obliged to retire into Sicily, where he died.

To the Pelagians succeeded the Semipelagians, who rejected the doctrines of the former with respect to original sin and the power of free will to do any good.[3] They owned that man had need of the grace of God to persevere in welldoing; but they believed that the beginning of good will and faith did not necessarily depend upon grace; for that man, by the mere force of nature, might desire to do good, and that God seconded that good will by his assistance, which depended upon liberty, and was given to all men. Besides these, they maintained some other peculiar tenets. The origin of some of their opinions is founded in this, that some of the books which were written by St Augustin in his last years, with respect to the controversies which arose in the monastery of Adrumetum, relative to correction, grace, and predestination, having been carried into Gaul, happened to give offence to several persons, and particularly to the monks of Lerins, who considered his doctrines as hostile to that of free will. This led them to think and to maintain, that, in order to be saved, it was necessary to leave to man the power of knowing and desiring good by the force of nature, so that the beginning might come from man. Several considerable persons in Gaul, and even some bishops, but particularly the priests, were of this opinion. Cassian, deacon of Constantinople, and afterwards priest of Marseilles, authorized it in his conferences; and Faustus, bishop of Riez, supported it very strenuously. From its very first appearance, St Augustin stood up to oppose this doctrine, and was supported by Prosper and Hilarius. Pope Celestin complained to the bishops of Gaul, that they suffered their priests to speak ill of the doctrines of St Augustin; Popes Gelasius and Hormisdas condemned the books of Faustus; and, last of all, the council of Orange, held in 529, condemned particularly the principal tenets of the Semipelagians, and put an end at that time to the controversy, about a hundred years after the death of St Augustin.

Semipelagians.

The Semipelagians were very numerous; and their doctrines, though variously explained, were received in many of the monastic schools in Gaul, whence they spread themselves far and wide throughout Europe. With respect to the Greeks and other Christians of the East, we may remark, that they had adopted the Semipelagian tenets, even before they were promulgated in Gaul by Cassian and Faustus.

After the period, however, at which the Semipelagian doctrines were condemned in the council of Orange, we find but little notice taken of this sect by historians. Although its tenets were maintained by a few in the succeeding centuries, the sect could boast of no eminent leaders, and sunk into obscurity. In the beginning, indeed, of the Reformation, some of the Pelagian tenets were again brought into circulation. Every one is acquainted with the hostility of Luther to the doctrine of free will, who went so far into the opposite extreme as to entitle one of his works against the celebrated Erasmus on this subject, *De Servo Arbitrio*. But notwithstanding that Luther was their leader, this doctrine of his was not adopted by some of the most eminent of the reformers. His learned friend, the mild and worthy Melancthon, although he at first, either from not having sufficiently considered the subject, or because this doctrine was so unpalatable to the great body of the reformers on account of the authority of Luther, joined with Luther in his hostility to the doctrine of free will so far as to say that free will could have no effect under the influence of grace, shortly afterwards changed his opinion so as to run into the opposite extreme. For although Luther at his outset had affirmed, that the prescience of God annihilated free will in all his creatures, he was so softened down into moderation at the time of the drawing up of the famous Confession of Augsburg, as to allow Melancthon, who composed it, to insert these words, "that it was necessary to allow free will to all who possessed the use of reason, not however in such things as regarded God, which they could not commence, or at least which they could not complete, without his assistance and grace, but in the affairs or works of the present life solely, and in order to perform their duty towards society."[4] In this passage two truths are clearly admitted: First, that there is free will in man; and, secondly, that of itself it has no efficacy in such works as are purely Christian or religious. But although this be evident, and although it would seem as if he attributed the efficacy of religious works solely to the grace of God, yet the restricting words "at least," show that he was of opinion that free will, by its own natural force and efficacy, though it could not complete, could at least commence, Christian or religious works, without the assistance of grace.

[4] See the 18th article, and Melancthon's Apology.

To such of our readers as are acquainted with ecclesiastical history, it is unnecessary to remark, that this was one of the leading tenets of the Semipelagians. But Melancthon did not stop here. It is true, that, in order to keep well with the reformers, he was obliged, in those public instruments which he drew up, to insinuate rather than avow his partiality for the doctrine of free will, the exercise of which, we see, he confined, in the Confession of Augsburg, to such actions merely as regarded civil life and our duties to society. In the Saxon Confession of Faith, however, he proceeds a step farther, and says, "that the will is free; that God neither wishes for, nor approves, nor co-operates in the production of sin; but that the free will of man and of the devils is the true cause of their sin and of their fall." Many, no doubt, will be of opinion, that Melancthon merits praise for having thus corrected Luther, and for having more clearly expressed his own opinion, than he had done in the Confession of Augsburg. He even proceeds farther, and extends the exercise of free will to religious or Christian works. For after having explained in the Saxon Confession of Faith the nature of free will, and the manner in which it makes a choice, and having also shown that it is not of itself sufficient in those works, or actions, which regard a future life, he affirms twice "that the will, even after having received the influence of the Holy Spirit, does not remain idle;" that is to say, it is not merely passive under the influence of grace, but can reject it, or co-operate with it, at pleasure. Necessity, it is true, obliged him to express his opinion rather obscurely. But what he insinuates only in these last-quoted words, is clearly and fully expressed in one of his letters to Calvin. "I had," says he, "a friend who, in reasoning upon predestination, believed equally the two following things; namely, that every thing happens among men as it is ordained by Providence, but that there is, nevertheless, a contingency in actions or in events. He confessed, however, that he was unable to reconcile these two things. For my part," continues Melancthon, "who am of opinion that God neither wishes for nor is the cause of sin, I acknowledge this contingency in the feebleness of our judgment, in order that the ignorant may confess that David fell of himself, and voluntarily, into sin; that he had it in his power to preserve the grace of the Holy Spirit which he had within him; and that in this combat or trial it is necessary to acknowledge some exercise or action of the will."[1] This opinion he confirms and illustrates by a passage from St Basil, where he says, "Have but the will or the inclination, and God is with you." By these words Melancthon seems to insinuate, that the will is not only active in the works of religion, but even begins them without grace. This, however, was not the meaning of St Basil, as is evident from several other parts of his writings; but that it was the opinion of Melancthon, appears fully from this passage, as well as from that which we have cited from the Confession of Augsburg, in which he insinuates that the error is not in saying that the will can of itself commence, but in thinking that it can, without grace, finish or complete religious or Christian works. Thus it appears, that he considered the will as capable of rejecting the influence of grace, since he declares, that David could preserve the Holy Spirit when he lost it, as well as he could lose it when he kept it within him. But although this was his decided opinion, he durst not avow it fully in the Saxon Confession of Faith, but was obliged to content himself with insinuating it gently in these words: "The will, even after receiving the grace of the Holy Spirit, is not idle or without action." All this precaution, however, was insufficient to save Melancthon from censure. Francowitz, better known by the name of Illyricus, being jealous of him, and his enemy, by his influence with his party procured the condemnation of these words of the Saxon Confession, and of the passage from St Basil, at two synods held by the reformers. At the same time that one party of the Lutherans were unwilling to adopt Melancthon's opinion, "that the will is not passive when under the influence of grace," we are at a loss to think how they could deny it, since they almost unanimously confess, that a person under the influence of grace may reject and lose it. This opinion is avowed in the Confession of Augsburg and in Melancthon's Apology. It was even, long after that, decided upon anew, inculcated strongly in their book of Concord, and brought frequently against them by their opponents as a proof of inconsistency and contradiction.

These are not the only instances in which the Lutherans were charged with Semipelagian principles. One of the ablest and the most learned of their opponents, we cannot help thinking, had in more than one instance made good the charge against them. To prove this we need only refer to the remarks that have been made on the eight celebrated propositions in the third book of Concord, relative to the co-operation of the will with grace. According to the first seven of these propositions, an attentive listening to the preaching of the word of God produces grace; and according to the fifth, any man, even a libertine or an infidel, is free, or has it in his power, to listen attentively to the preaching of the word of God. He has it then in his power to give to himself that which to him is productive of grace, and may thus be the sole author of his own conversion or regeneration. In the eighth proposition it is affirmed, that we are not permitted to doubt that the grace of the Holy Spirit, even though it may not be felt, does accompany an attentive hearing of the word of God; and, to do away every doubt about the species of attention which they mean, we must observe, that they speak of attention inasmuch as it precedes the grace of the Holy Spirit, and of that attention which, in consequence of its dependence on free will, we have it in our power to bestow upon the word or not, just as we please. It is the exercise of this free attention which they say operates grace. But here it would seem that they were in extremes; for, as they said, upon the one hand, that when the Holy Spirit begins to move us we act not at all, so they maintained, on the other, that this operation of the Holy Spirit, which converts us without any co-operation on our part, is necessarily attendant upon an act of our wills, in which the Holy Spirit has no share, and in which our liberty acts purely by its natural force or power. Such of our readers as are anxious to examine the progress of the Pelagian and Semipelagian principles after the dawn of the Reformation, we must refer to the works of the principal reformers and to those of their adversaries, as well as to the different writers upon ecclesiastical history.

SEMIRAMIS, queen of Assyria, reigned about five generations before Nitocris, and constructed some wonderful works to restrain the waters of the Euphrates within its banks. Diodorus gives a more detailed account of her, which is copied principally from Ctesias. Omitting the fabulous statements respecting her youth, we there find that she had a son, Ninyas, from Ninus; and that after her husband's death she thought herself capable of governing the empire. She founded the city of Babylon, which she surrounded by walls of immense strength, and adorned by very wonderful buildings. On the top of the temple of Belus she placed three statues of massive gold, and from the middle of the temple rose a tower higher than the highest pyramid of Egypt. Some have thought that this was the tower of Babel. She made warlike expeditions against the Medes, Persians, Libyans, and Æthiopians. She is said to have executed many wonderful works in different parts of her kingdom; changing mountains into plains, and constructing canals and palaces. Hearing of the riches and power of India, she determined to make war on that kingdom, and prepared an immense army; but she was in a great measure unsuccessful, and returned with the loss of nearly her whole army. When she reached Babylon, her son laid snares for her; and as it had been predicted by the oracle of Jupiter Ammon that she would disappear from the world when this took place, the prediction was fulfilled. Semiramis was no more seen, having died in the sixty-second year of her age, and the forty-second of her reign.

SEMITONE. See MUSIC.

SEMLIN, a city of the Austrian dominions, on the frontier towards Turkey. It stands in that district which forms a part of the military colonies of Austria, distinguished by the name of the Sclavonian boundary. It is situated on a point of land where the river Drave falls into the Danube; and it is strongly fortified, and tolerably well built. The Catholics have one church and four chapels; the Greeks have two churches, over which a propapa presides. There are a convent of Franciscans, a German normal school, a hospital, a Jews' synagogue, and 1250 dwelling-houses, with about 8700 inhabitants. At this place is the lazaretto, where all persons arriving from Turkey must exhibit bills of health, and perform quarantine. In a meadow between this place and Belgrade a daily market is held, where two rows of palisades separate the dealers, and where sentinels are continually on the watch, to see that no hazardous communication takes place; and all goods bought from the Turks must be exposed to the air and fumigated. It is a place of considerable traffic with Turkey. The communication by steam-vessels between Vienna and Constantinople has given a stimulus to its commerce, and is likely to occasion a much greater increase. There are now more than 120 mercantile houses established here, some of which are Greek, others Turkish, and a part Austrian. There are 380 persons employed in manufactures, and more than 100 hotels or taverns. The colonists regimented here form the Peterwarden branch of the army. Long. 20. 19. 39. E. Lat. 44. 51. 22. N.

SEMUR, an arrondissement of the department of Côte d'Or, in France, which extends over 598 square miles. It is divided into six cantons, and these into 145 communes, with a population, in 1836, of 70,505 inhabitants. The capital is the city of the same name, standing on a rock washed on three sides by the river Armançon. It contains a fine collegiate church, built in 1065, a public library with 12,000 volumes, and 920 houses, with 4035 inhabitants, who make some woollen goods, and trade largely in wine, cattle, corn, and hemp. Long. 3. 30. E. Lat. 47. 18. N.

SEMYLE, a fortress of Hindustan, in the province of Assam, situated on the banks of the Brahmapootra river, which it commands. It was taken by the Mahommedans in the year 1662.

SENAN-FOU, a city of China, of the first rank, in the province of Koeitchoo, situated on a fine river, in an extensive plain, surrounded on all sides by mountains, among which dwell a barbarous race, who have little intercourse with the Chinese. Long. 107. E. Lat. 27. 56. N.

SENATE, in general, is an assembly or council of senators, that is, of the principal inhabitants of a state, who have a share in the government.

The senate of ancient Rome is of all others the most celebrated. It exercised no contentious jurisdiction, but appointed judges, either from among the senators or knights, to determine processes. It also appointed governors of provinces, and disposed of the revenues of the commonwealth. Yet the whole sovereign power did not reside in the senate, since it could not elect magistrates, make laws, or decide of war and peace; for, in all these cases, the senate was obliged to consult the people.

The senate, when first instituted by Romulus, consisted of a hundred members; to whom he afterwards added the same number when the Sabines had migrated to Rome. Tarquin the ancient made the senate consist of three hundred, and this number remained fixed for a long time; but afterwards it fluctuated greatly, and was increased, first to seven hundred, and afterwards to nine hundred, by Julius Cæsar, who filled the senate with men of every rank and order. Under Augustus the senators amounted to a thousand; but this number was reduced, and fixed at six hundred. The place of senator was always bestowed upon merit. The monarchs had the privilege of choosing the members; and after the expulsion of the Tarquins, it was one of the rights of the consuls, until the election of the censors, who from their office seemed most capable of making choice of men whose character was irreproachable, whose morals were pure, and whose relations were honourable. Only particular families were admitted into the senate; and when the plebeians were permitted to share the honours of the state, it was then required that they should be born of free citizens. It was also required that the candidates should be knights before their admission into the senate. They were to be above the age of twenty-five, and to have previously passed through the inferior offices of quæstor, tribune of the people, edile, prætor, and consul.

The senate always met on the first of January for the inauguration of the new consuls; and in all months, universally, there were three days, the kalends, nones, and ides, on which it regularly met. But it always met on extraordinary occasions, when called together by consul, tribune, or dictator.

To render their decrees valid and authentic, a certain number of members was requisite, and such as were absent without some proper cause were always fined. In the reign of Augustus, four hundred senators were requisite to make a senate. Nothing was transacted before sunrise or after sunset. In their office the senators were the guardians of religion; they disposed of the provinces as they pleased; they prorogued the assemblies of the people; they appointed thanksgivings, nominated their ambassadors, and distributed the public money; and, in short, they had the management of every thing political or civil in the republic, except the creating of magistrates, the enacting of laws, and the declaration of war or peace, which were confined to the assemblies of the people.

SENATOR, in general, denotes a member of some senate.

The dignity of a Roman senator could not be supported without the possession of eighty thousand sesterces, or about L.7000 English money; and therefore such as squandered away their money, and reduced their fortune below this sum, were generally struck out of the list of senators. This regulation was not made in the first ages of the republic, when the Romans boasted of their poverty. The senators were not permitted to be of any trade or profession. They were distinguished from the rest of the people by their dress. They wore the laticlave, half-boots of a black colour, with a crescent or silver buckle in the form of a C; but this last honour was confined only to the descendants of those hundred senators who had been elected by Romulus, as the letter C seems to imply.

Among us, senator is a member of parliament. In the laws of Edward the Confessor, we are told that the Britons called those senators whom the Saxons called afterwards aldermen and borough-masters, though not on account of their age, but their wisdom; for some of them were young men, but very well skilled in the laws. Kenulph king of the Mercians granted a charter, which ran thus: *Consilio et consensu episcoporum et senatorum gentis suæ largitus fuit dicto monasterio*, &c. In Scotland the lords of session are called senators of the college of justice.

SENATUS CONSULTUM, a part of the Roman law. When any public matter was introduced into the senate, which was always called *referre ad senatum*, any senator whose opinion was asked was permitted to speak upon it as long as he pleased; and on that account it was often usual for the senators to protract their speeches until it was too late to determine. When the question was put, they passed to the side of that speaker whose opinion they approved, and a majority of votes was easily collected, without the trouble of counting the numbers. When the majority was known, the matter was determined, and a *senatus consultum* was immediately written by the clerks of the house, at the feet of the chief magistrates, and it was signed by all the principal members of the house. When there was not a sufficient number of members to make a senate, the decision was called *senatus auctoritas;* but it was of no force if it did not afterwards pass into a *senatus consultum.*

The *senatus consulta* were at first left in the custody of the kings, and afterwards of the consuls, who could suppress or preserve them; but about the year of Rome 304 they were always deposited in the temple of Ceres, and afterwards in the treasury by the ediles of the people.

SENDWAH, a town of Hindustan, in the Mahratta territories, and province of Khandesh, eighty-two miles from Boorhanpoor. Long. 75. 8. E. Lat. 21. 48. N.

SENECA, LUCIUS ANNÆUS, a Stoical philosopher, was born at Cordoba, in Spain, about the beginning of the Christian era, of an equestrian family, which had probably been transplanted thither in a colony from Rome. He was the second son of Marcus Annæus Seneca, commonly called the Rhetorician, whose remains are printed under the title of *Suasoriæ et Controversiæ, cum Declamationum Excerptis;* and his youngest brother Annæus Mela, for there were three of them, had the honour of being father to the poet Lucan. He was removed to Rome, together with his father and the rest of his family, while he was yet in his infancy. There he was educated in the most liberal manner, and under the best masters. He learned eloquence from his father; but his genius rather leading him to philosophy, he put himself under the stoics Attalus, Sotion, and Papirius Fabianus, men famous in their way, and of whom he has made honourable mention in his writings. It is probable, too, that he travelled when he was young, since we find him, in several parts of his works, particularly in his *Quæstiones Naturales*, making very exact and curious observations upon Egypt and the Nile. But this, though entirely agreeable to his own humour, did not at all correspond with that plan of life which his father had drawn out for him; and therefore he forced him to the bar, and put him upon soliciting for public employments, so that he afterwards became quæstor, prætor, and, as Lipsius will have it, even consul.

In the first year of the reign of Claudius, when Julia the daughter of Germanicus was accused of adultery by Messalina, and banished, Seneca was also banished, being charged as one of the adulterers. Corsica was the seat of his exile, where he lived eight years, "happy in the midst of those things which usually make other people miserable" (*inter eas res beatus quæ solent miseros facere*); and he wrote his books of consolation, addressed to his mother Helvia, and to his friend Polybius, and perhaps some of those tragedies which go under his name. Agrippina being married to Claudius upon the death of Messalina, she prevailed with the emperor to recall Seneca from banishment, and afterwards procured his appointment as tutor to her son Nero, whom she designed for the empire. Africanus Burrhus, a prætorian præfect, was joined with him in this important charge; and these two preceptors, who were intrusted with equal authority, had each his respective department. By the bounty and generosity of his royal pupil, Seneca acquired that prodigious wealth which rendered him in a manner equal to kings. His houses and walks were the most magnificent in Rome. His villas were innumerable; and he had immense sums of money placed out at interest in almost every part of the world. The historian Dio reports him to have had L.250,000 sterling at interest in Britain alone, and reckons his calling it in all at once as one of the causes of a war with that nation.

All this wealth, however, together with the luxury and effeminacy of the court, does not appear to have had any ill effect upon the temper and disposition of Seneca. He continued abstemious, exact in his manners, and, above all, free from the vices so commonly prevalent in such places, flattery and ambition. "I had rather," said he to Nero, "offend you by speaking the truth, than please you by lying and flattery" (*maluerim veris offendere, quam placere adulando*). How well he acquitted himself in quality of preceptor to his prince, may be known from the first five years of Nero's reign, which have always been considered as a perfect pattern of good government; and if that emperor had but been as observant of his master through the whole course of it as he was at the beginning, he would have been the delight, and not, as he afterwards proved, the curse and detestation, of mankind. But when Poppæa and Tigellinus had got the command of his humour, and hurried him into the most extravagant and abominable vices, he soon grew weary of his master, whose life must indeed have been a constant rebuke to him. Seneca, perceiving that his favour declined at court, and that he had many accusers about the prince, who were perpetually whispering in his ear the great riches of Seneca, his magnificent houses and fine gardens, and what a favourite, through the means of these, he was grown with the people, made an offer of them all to Nero. Nero refused to accept them. This, however, did not hinder Seneca from changing his way of life; for, as Tacitus relates, he "kept no more levees, declined the usual civilities which had been paid to him, and, under pretence of indisposition, or some engagement or other, avoided as much as possible appearing in public."

In the mean time Nero, who, as it is supposed, had despatched Burrhus by poison, could not be easy till he had also rid himself of Seneca; for Burrhus was the manager of his military concerns, and Seneca conducted his civil affairs. Accordingly, he attempted, by means of Cleonicus, a freedman of Seneca, to take him off by poison; but as this did not succeed, he ordered him to be put to death, upon an information that he was privy to Piso's conspiracy against his person. Not that he had any real proof of Seneca's being concerned in this plot, but only that he was glad to lay hold of any pretence for destroying him. He left Seneca, however, at liberty to choose his manner of dying; and the latter caused his veins to be opened immediately. His wife Paulina, who was very young in comparison of himself, had yet the resolution and affection to bear him company, and therefore ordered her veins to be at the same time opened; but as Nero was not willing to make his cruelty more odious and insupportable than there seemed occasion for, he gave orders to have her death prevented. Her wounds were therefore bound up, and the blood stopped, just in time enough to save her; though, as Tacitus says, she looked so miserably pale and wan all her life afterwards, that it was easy to read the loss of her blood and spirits in her countenance. In the mean time, Seneca, finding his death slow and lingering, desired Statius Annæus, his physician, to give him a dose of poison, which had been prepared some time before in case it should be wanted; but this not having had its usual effect, he was carried to a hot bath, where he was at length

Senegal.

stifled with the steam. He died, as Lipsius conjectures, in the sixty-third or sixty-fourth year of his age, and in about the tenth or eleventh of Nero's reign. Tacitus, on mentioning his death, observes, that, as he entered the bath, he took of the water, and with it sprinkled some of his nearest domestics, saying, " that he offered these libations to Jupiter the Deliverer." These words are an evident proof that Seneca was not a Christian, as some have imagined him to have been; and that the thirteen epistles from Seneca to St Paul, and from St Paul to Seneca, are supposititious pieces. The writings of Seneca, excepting his books of Physical Questions, are chiefly of a moral kind. They consist of a hundred and twenty-four epistles, and distinct treatises on Anger, Consolation, Providence, Tranquillity of Mind, Constancy, Clemency, The Shortness of Life, Happiness, Retirement, and Benefits. A number of tragedies are extant under the name of Seneca, and written in a vicious style; but it is uncertain whether the whole or any part of them were his. The first good edition of his acknowledged works was published by Justus Lipsius, which was succeeded by the *Variorum*, 1672, three vols. 8vo, and others. Of the tragedies, the best are that of Scriverius, 1621, the *Variorum*, 1651, and Schrœder's, 1728, 4to.

SENEGAL, a great river of Western Africa, which, like the Gambia and Rio Grande, has its source in a group of mountains situated a short distance to the north-west of Temboo, in Foota Jallon. Mollien places the source of the Ba Fing, the middle branch of the Senegal, in latitude 10° 10′ north, longitude 11° 18′ west; and that of the Falemé, the western branch, in latitude 10° 20′ north, and longitude 11° west. This traveller thus describes the spot whence the former mighty stream issues. " Ascending the stream, I perceived two basins, one above the other, from which the water gushed forth; and still higher a third, which was only humid, as well as the channel that led to the basin immediately below it. The negroes consider the upper basin as the principal source of the river. These three springs were situated about the middle of the side of the mountain. In the rainy season, two ponds, at equal distances above the upper source, supply it with water by two deep channels. The Senegal, called Baleo (Black River) in the Poula language, and Bafing in Mandingo, which has the same signification, or Foura, which means simply the river, runs at first from north to south, then passes at a little distance to the south of Teembo, and afterwards pursues a western direction," which, we may add, it maintains till its embouchure in the Atlantic Ocean. We are indebted chiefly to the enterprises of the French for our knowledge of the Senegal, of which river they were long the sole masters as high as the cataract of Feloo, and at the mouth of which they fixed the capital of the factories they possessed from Arguin to Sierra Leone. Amongst the copious descriptions of this great river, we avail ourselves of that of M. Golberry. The course of the Senegal, from its mouth to the rock of Feloo, the boundary of French navigation, is nearly 280 leagues, although the distance in a direct line is not more than 160 leagues. This cataract, which is situated sixty miles above Galam, is the principal one on the river; forty miles above it is that of Govinea. The windings of the Senegal are remarkably tortuous and circuitous. As far as the rock of Feloo, the country through which it flows is a level, having so small an inclination that a very slight interruption is sufficient to divert the course of the stream, so that it frequently seems on the point of returning to its source. It is only navigable during the rainy season; but Adanson informs us that he found the river, at its greatest ebb, from twenty to thirty feet deep at Podor, sixty leagues up, where, however, the influence of the tide reaches. The greatest rise of the tide at the mouth of the river is two feet and a half. Here there is a bar, which prevents the entrance of all vessels drawing ten feet of water, although immediately within it there is sufficient depth for ships of any size. The entrance of the bar has shifted from time to time, owing to the influence of opposing currents. Sand-banks and rocks embarrass the navigation; enormous trees and portions of the bank are continually borne down by the current; frequent hurricanes and storms are encountered, followed by dead calms; and the burning atmosphere, when not violently agitated, becomes extremely oppressive, so that the voyage into the interior has always proved highly detrimental to Europeans. Were it not for these perils, it would be particularly interesting to the naturalist, as the extremely picturesque banks present a rich variety of the noblest productions of the vegetable kingdom, whilst the extensive forests abound with all kinds of wild animals. Amongst others, elephants are seen in large troops. In the shallow parts of the river are a vast number of hippopotami, and caymans of prodigious size. The whole length of the river is estimated at 800 miles, its embouchure taking place in latitude 16° 5′ north. About eight leagues below Galam, at the village of Tafalisga, the Senegal receives the Falemé, which may be navigated during the rainy season by vessels of sixty tons. The easterly and inferior arm of the Senegal, called the Kokora, is formed of a number of streams which rise between 5° and 7° of west longitude, and 12° and 13° of north latitude. The Ba Fing and the Kokora unite a short distance above Feloo, and the combined streams then take the name of the Senegal.

Senegambia.

Isle of SENEGAL, sometimes called *Saint Louis*, is a small island in the mouth of the river Senegal, and, according to Maskelyne's tables, is situated in long. 16. 31. W. and lat. 15. 53. N.

SENEGAMBIA, a large country of Africa, on the Atlantic Ocean, lying between the rivers Senegal and Gambia, from the mouth of the Nunez to Portendik, with several adjoining districts, and extending from 8° to 18° 20′ of north latitude, and from about 5° to 17° 30′ 30″ of west longitude. It is bounded on the west by the Atlantic Ocean, on the south by Guinea, on the east by Nigritia or Soudan, and on the north by the great desert of Sahara. This fine territory lies upon the western and northern declivities of the mountains of Kong, which here stretch from east to west in some degree parallel with the Gulf of Guinea, and is separated by the great valley of the Quorra or Niger from that part of the northern table or terrace land in which the elevated portion of Africa sinks into Soudan. The interior of this extensive tract of high land, called High Soudan, whose southern limit towards the Gulf of Guinea more especially bears the name of the Kong Mountains, is wholly unknown to us; but its general height is not more than two thousand feet above the level of the sea. It appears to be fine pasture-land, to have an excellent climate, and to support a vast number of African tribes. Surrounding it on the west and north, are those table-lands called the Wildernesses of Jallonkadu, which are only inhabited by wild beasts and reptiles, and through which Mungo Park travelled five days without seeing the face of man. But beyond these to the north and west extends a fertile country, rich in streams, which descend to the coast in a westerly or north-westerly direction. Immediately north from Sierra Leone the fruitful part of the coast is narrow, but enlarges as we proceed in the same direction, especially where the mountains on the middle of the Gambia fall back to the east; and on the Senegal it expands into broad plains, which reach to the foot of the highlands already mentioned. The principal capes upon the coast are called Verga, Roxo, St Mary, and Verd. The low parts of this tract of country are reckoned amongst the hottest on the globe, the average temperature throughout the year being 63° Fahrenheit; but the heat is of course moderated on the mountainous districts and high table-lands. From November till the end of March is the dry and healthy season, during which the nights are cool, and the east and north-east winds prevail. Between the dry and the wet season a period intervenes when those terrific visitations, the tornadoes, prevail, and which are in general accompanied by violent thunder-storms. During the rainy season the heat is suffocating and the air loaded with humidity. Bad fevers are then common, and multitudes of insects and crawling vermin swarm in the air and on the ground, the torment and terror of man. Towards the end of the rainy season the harmatta begins to blow from the Sahara, which, although troublesome in itself, dries up the soaked ground, and purifies the air from its pernicious miasmata.

The mountains of Kong are more rich in water than any other part of Africa. Great numbers of rivers of various sizes descend its declivities, and after traversing large tracts of country, find their embouchure in the Atlantic Ocean. The most important are, the Rio Grande, the Gambia, and the Senegal, each of which is described under its own head; the Rio Nunez, which originates in the high table-lands in the interior, and, without having a very long course, is abundant in water; the Katherine and the Domingo, or the Upper and Lower Geba, originating in the table-land of Mandingo, and forming during its course a large lake, whence a considerable river flows to the sea, where it has deposited an extensive delta. From this point to the embouchure of the Gambia, numerous rivers or arms of the sea intersect the flat coast like net-work, so that between 10° and 14° of north latitude it appears as if partitioned into numberless islands. In front of this maritime tract extends a long bank of sand, out of which the islands called the Bissagos have been formed.

The inhabitants consist of Moors and Negroes, which races present a remarkable contrast in respect to their physiognomy, hair, colour, manners and customs, and the like. To the last-named people belong the Jallofs, situated between the Senegal and the Gambia. They are a fine specimen of the negro. Their colour is of a deep glossy black, of which they are very proud, and also of their ancient origin. The Mandingoes, who are partly Mahommedans, are situated on the Gambia; but, on account of their trade, they have colonies scattered over the interior of Africa. The Soosoos lie between the sources of the Gambia and the Senegal. The Feloops are scattered along the banks of the Lower Gambia, in Casamansa, and St Domingo. The Serawoollies occupy the kingdoms of Galam and Senegal. The Serreres, or Seraires, are distributed in little republics on the borders of the kingdom of Kayor; and the Pappels are situated on the south side of the St Domingo, and on the Bissagos islands. The Foulahs, on the Senegal, the same race which in Soudan is called the Fellatahs, are not true negroes; they have silken hair, and a reddish or olive complexion. Amongst those tribes which have more recently become known to us, we have to mention the Timmanees, whose principal place is Rokon, on the river Rokelle, some miles distant from the colony of Sierra Leone. From their youth they accustom themselves so much to drinking palm wine, that they get into a relaxed and effeminate state at a very early age. The Koorankas are mixed with the Mandingoes. They go constantly armed, usually with a firelock and dagger. Lastly, the Soolimas are a gay, thoughtless, stirring race, whose principal town is called Falaba, not far from the sources of the rivers Rokelle and Kabba. The principal languages spoken are the Jallof, Mandingo, Serawool, Soosoo, Arabic, Portuguese, and many varying dialects formed out of these.

In the trade of Senegambia, the English, French, Dutch, Danes, and North Americans participate. The exports consist of slaves, which, however, are of less value than those of Guinea; skins of tigers, and other animals; wax, hides, ivory, gums, cotton, and the like. England obtains ivory and gold from the countries situated between Cape Blanco and Cape Negro, and gives in return such of her own manufactures as are required. The trade in gold amounts to 30,000 ounces yearly.

Of the numerous kingdoms and countries into which the vast territory of Senegambia is partitioned, there will be found described in this work, each under its own head, BAMBOOK, BISSAGOS, BONDOO, and KAJAAGA. There still remain unnoticed a considerable number, of which we shall here present a brief account.

1. The land of the Foulahs consists of a number of provinces or kingdoms, interspersed throughout the tract comprehended between the mountainous border of the country of Sierra Leone on the west and that of Timbuctoo on the east, as also a large tract on both sides of the Senegal, and several districts on the Gambia; these provinces being insulated from each other in a very remarkable manner. The principal of the Foulah states is that within Sierra Leone, and of which Temboo is the capital. The next in order appears to be that bordering on the south of the Senegal river, and on the Jallofs. Others of less note lie between the rivers Gambia and Falemé; Foola-doo and Brooko are situated along the upper part of the Senegal; Wassela, beyond the upper part of the Niger; and Massina, lower down on the same river, adjoining Timbuctoo on the west. Amongst other districts belonging to the Foulahs may be mentioned Morfil or Ivory Island, Bilbos, and other islands of the river Senegal. On the former is a French factory, at a place called St Podhor, which is fortified. A trade in gum is here carried on. Not far from the sources of the Senegal, and three hundred and seventy miles inland, are situated, on the mountains of Kong, the towns of Temboo, which has eight thousand inhabitants, and Ladi, which has five thousand inhabitants. In both are Maraboot schools; and some trade is carried on in iron, silk, and leather. The other towns it is unnecessary to enumerate, nor can the whole number of inhabitants in the land of the Foulahs be ascertained. 2. Ludamar, situated on the borders of the Sahara. It is ruled over by a Moorish king, who resides at Benowm. On the borders of the neighbouring kingdom of Kaarta lies Tsharra, where the unfortunate Houghton met his fate. 3. The land of the Jallofs or Yolofs, comprising four territories or governments, and situated near the sea-coast, in the region between the rivers Senegal and Gambia. This country is rich in provisions, cattle, and poultry, and flourishes under a more regular administration than that of the adjoining states. The people manufacture cotton goods. The chief ruler bears the title of emperor of the Jallofs, and resides at Hikarkor, the principal town. The states separated from the Jallof empire, such as those of Baol and Cayor, are governed by a prince, who bears the title of Damel. 4. Sin, or Barb-Sin, for the most part situated on the north of the Gambia, has a hundred and forty square leagues of territory, and contains sixty thousand inhabitants. The regent, who is called Boor, has his principal seat at Joal, a seaport, formed by the mouth of the river of that name. There is a trade carried on in cattle, poultry, rice, slaves, wax, hides, and ivory. 5. Boorsali, or Salum, situated on a river of the same name, which discharges itself into the Atlantic in latitude 13° 44′ north. It comprehends a surface of 1500 square miles, and contains 300,000 inhabitants. The principal place, and the residence of the king, is called Calyoon. Upon the Gambia are situated Kahan or Cahon, and Cower or Kayee, where cotton-weaving is carried on. 6. Bar or Barrah, situated at the mouth of the Gambia, has an area of 700 square miles, and contains 200,000 inhabitants, who are Mahommedans. There are here public schools, so that it must have risen above the barbarism of most of the surrounding states. The country is tributary to Salum, and is governed by regents of circumscribed authority. The principal town is called Ba-

rinding; the others are Albreda, on the river Gambia, which has 7000 inhabitants, and Jellifree, on the same river, a Portuguese settlement, where there is also an English factory. Salt is the principal article of trade. 7. Badiboo, situated to the east of the former, on the right bank of the Gambia, is about 600 square miles in extent. The capital is a small place of the same name. The population of the country may amount to 150,000. 8. Yani, also situated on the Gambia. The chief towns are Pisania, where there is an English factory, and Jonkadouda, where are several other European factories. There is a trade carried on in gold, ivory, and other products of the country. 9. Wally, or Bembook, is situated to the east of the former, and is rich in wood, corn, rice, garden-stuffs, cotton, indigo, cattle, and fish. Malchme is the chief town, where resides the king, who exercises a limited sovereignty. 10. Wooli, a Mandigo kingdom, extends along the northern bank of Gambia, between Salum and Bondoo. The country is generally covered with extensive woods; the soil is everywhere fertile, producing cotton, tobacco, and esculent vegetables; and there are a number of towns situated in the valleys, which are the tracts chiefly cultivated. Medina, the capital, is a walled town, the residence of the king and state officers. It does not appear that this is a place of any considerable trade. 11. Gedumah, situated on the northern bank of the Senegal, and inhabited by nomadic Moors, who here find pasture for their cattle. It appears to be destitute of either town or village. 12. Combo, Foini, Caen, Jemaroa, Tommani, and Kolar, are the names of small kingdoms or territories, generally productive in rice, wax, goats, poultry, and the like, and in the principal towns of which are European factories. 13. The land of the Soosoos, which is situated between the sources and head waters of the Senegal and Gambia. This country is inhabited by an active race of men, who appear to live under a monarchy. From the conflicting statements of travellers and geographers, it seems doubtful if these people do not form a part of the Foulahs. 14. The land of the Feloops, situated upon the banks of the Casamanza, and on the upper course of the Vintain, is about twenty-five leagues in length by fifteen in breadth. The country is very fertile, and the inhabitants rear cattle, which they defend with much courage against lions and other wild animals, with which their forests abound. Rice, goats, poultry, bees' wax, and honey, are abundant, and partly exported. The population may amount to fifty thousand, who inhabit about sixty villages. 15. Kaboo is a territory situated on the upper part of the rivers St Domingo and Geba. It is subject to a king, who trades with the Portuguese in slaves, gold, and ivory. His residence, which is in the chief town, lies on the lake from which the river Geba flows. The Portuguese have here a settlement. Kaboo is very fertile in rice, millet, maize, indigo, and cotton. It is inhabited by a mixture of nations, chiefly Pagan Mandingoes, whose language prevails. 16. The important kingdom of Foota Torra, which extends considerably both to the north and south of the middle Senegal, but whose interior has not yet been explored by Europeans. There are a number of other kingdoms or territories in Senegambia, but they do not require particular notice. The most distinguished are the kingdom of Jallonkadoo, in which the river Senegal takes its rise; and the kingdom of Soolimana, which extends along the rocky Rokelle, and the Camaranca and Mungo.

Besides those places we have mentioned as possessing European factories, the English, French, and Portuguese have also settlements. The English have factories on the rich gum coast at Portendik, to the north of the Senegal; the island of James, situated a few miles from the mouth of the Gambia, with the fort of the same name; the island of Boolam, with a secure and spacious harbour, and formerly one of the Sierra Leone Company's stations, for promoting civilization amongst the Indians, for assisting in putting down the slave-trade, and for cultivating West Indian products; and the island of St Maria, on the Gambia, with twelve thousand inhabitants.

The French possess the island of St Louis or Senegal, at the mouth of the river of the same name, with 16,130 inhabitants, and the Fort St Louis, whence ships proceed on their voyage up the Senegal; but navigation is very much embarrassed by a dangerous bank across the mouth of the river. The trade between this place and the mother country was at one time very considerable, amounting to L.750,000 annually; and the English disposed of an equal amount of goods on the Gambia. At the French settlement a considerable quantity of cotton is still grown, and gum collected. The names of the other places are, the island of Goree, which is separated from the mainland by the canal of Dakar, 1500 toises in breadth. It is a great basaltic rock, with a town upon it, which bears the same name, and a fort, which bears that of St Michael. The French have also in the neighbourhood of Cape Verd a place called Riofresco. On the left bank of the Senegal is the settlement of Bakel, a hundred and five miles from St Louis, to which there is a steam-boat sent annually with goods. There are, besides, St Charles, formerly called Fort St Joseph; and the islands of Babaghee, Safal, and Geber.

The Portuguese possess St Cachao or Cacheu, situated on the north-east of the island of Bassao, at the mouth of the river St Domingo, in the kingdom of Koombo. It is fortified, has a Catholic church and a monastery, is the seat of a Portuguese governor, trades with the Cape Verd and Azore Islands, and contains 8000 inhabitants. The Portuguese also possess the island of Bissago, and the posts of Farim, Zeguichor, and Geba, which belong to the government of Cape Verd. (R. R. R.)

SENESCHAL (*Seneschallus*), derived from the German *sein*, "a house or place," and *scale*, "an officer," is a steward, and signifies one who has the dispensing of justice in some particular cases: as the high seneschal or steward of England; *seneschal de la hôtel de roi*, "steward of the king's household, seneschal or steward of courts." (*Co. Lit.* 61; Croke's *Jurisd.* 102; Kitch. 83.)

SENGBEST, a town of Persia, in the province of Khorassan, twenty-five miles south-east of Meshed.

SENGEN, a city of China, of the first rank, in Quangsee, situated in a small and mountainous district. Long. 107. 34. E. Lat 23. 24. N.

SENGOA, a village of Persia, in the province of Azerbijan, forty-eight miles south-east of Tabreez.

SENJEN, one of the largest islands of the kingdom of Norway, after Hindoen. It is separated from the continent by a narrow strait, and is about fifty miles in length and thirty-nine in breadth. It is surrounded by cliffs of more than 600 feet in height, which are covered with birch and pine trees; and, considering the climate, there are some tolerably good sections of pasture-land, upon which black cattle are reared. It comprehends three parishes, viz. Bergfiord cum Medfiord, with 370 inhabitants; Torask, with 350; and Tronoe, with 1560. There are two trading ports on the shore, Klowen and Gabostad, where small vessels repair.

SENLIS, an arrondissement of the department of the Oise, in France, which extends over 516 square miles. It contains seven cantons and 132 communes, with, in 1836, 78,790 inhabitants. The capital is the city of the same name, situated on the river Nonnette, an ancient place, with walls built at some remote period. The cathedral is also antique, and has the loftiest tower in France. It contains nine churches, and 950 houses, with 5016 inhabitants.

SENNA, a town of Persia, the capital of the eastern part of Kurdistan, known under the name of the province of Ardelan. It is situated in the bosom of a luxuriant valley, richly cultivated, and interspersed with orchards affording abundance of fruits of various kinds, namely, the peach, the apricot, the pear, apple, and cherry, besides producing tobacco and quantities of grain. It is a flourishing town, containing 8000 inhabitants, of which number 2000 are Jews, Armenians, and Nestorians, who trade to Mosul, Bagdad, and Ispahan. The town is surrounded by mountains, which are inhabited by wandering tribes of Kurds and Iliats. It is eighty miles south-east of Mosul. Lat. 35. 12. N.

SENNAAR, a country of Nubia, in Africa, forming that peninsula of land which lies between the two main branches of the Nile, immediately prior to their junction. From the confluence of the Bahr el Abiad, and the Bahr el Azrek, in north latitude 15° 34′ 40″, and east longitude 32° 11′ 25″, to the town of Sennaar, on the Bahr el Azrek, may be about a hundred and twenty miles; but the sway of the pasha of Egypt extends two hundred miles farther southward between the two rivers, so that the length of the country, which appears to have no other distinctive name but Sennaar, may be estimated at above three hundred miles. On account of its wedge-like shape, its breadth is various, from a point to a hundred and fifty or two hundred miles. Eastward from the Bahr el Azrek or eastern branch of the Nile, there is an immense tract of country nearly enclosed by the above-named river, and the Atbara or Tacazze, the great tributary of the Nile. In many maps and geographical works this is laid down as a part of Sennaar, and it certainly at one time bore that name. But it is now distinguished by the appellation of Atbari, and corresponds to the Meröe of the ancients, to which article the reader is referred. The territory included between the Abiad and the Azrek, and to which we limit the name of Sennaar, is usually called El Gezira, or the Island, because, in the season of the rains, the numerous streams which flow into these rivers from the mountains in the south encompass several districts with their spreading waters. But, viewed as a whole, the country has no pretensions to the name of island; for there is no large insulating stream cutting it off from the mainland. With more propriety, it is sometimes called Dar Fungi, or the land of Fungi, that is, the Conqueror, a negro tribe, which in 1504 descended from the interior of Ethiopia, and founded the kingdom of Sennaar. A race of hereditary monarchs, called Muck or Melek, continued to rule the country from that period till 1821, when the pasha of Egypt despatched an expedition into these regions, by which they were subdued. The former sovereign retired, on a pension (which was never paid), to the government of a small and obscure colony, over which he was not permitted to exercise any authority.

Sennaar is, for the most part, an elevated plain, which, except during the rainy season, is not only dry, but well ventilated by the breezes from the south and the east. These winds are generally cool, because they come either from the mountains of Abyssinia, or from the huge ridges that compose the Gebel el Gamara. The climate is healthy, except during the Khareef, the period which succeeds the rains; yet even then Sennaar is the most healthy of the Soudan possessions of the pasha. In summer the heat is represented as by no means oppressive, where there is any protection from the direct rays of the sun. The soil is capable of cultivation after the rains, when the doura is sown, the principal product of the country. This being reaped, the land is allowed to remain undisturbed till after the next rains, when the process is renewed. Camels, cattle, and sheep, are abundant in some parts, the plains frequently producing excellent pasture, and the superintendence of flocks and herds forming one of the chief occupations of the inhabitants. The woods abound in various kinds of birds, including ostriches, whose feathers constitute an article of trade. Elephants, lions, tigers, camelopards, monkeys, and other denizens of the forest, are found in Sennaar, and frequently carry off the cattle and sheep. There is likewise a rare animal called maraseen very abundant here. It is described as being in appearance "more like the hyena than the wolf," measuring six feet in length from head to tail, and standing above three feet in height. Guinea-fowl are very plentiful in the woods and on the banks of the rivers.

Sennaar, the capital of the country, formerly a large, well-built, and populous city, is now little more than a heap of ruins. In the days of Poncet it contained 100,000 inhabitants; but they are now reduced to 9000. It is situated on the western bank of the Bahr el Azrek, in a bare plain, and presents the appearance of a long, low, straggling ruin. There are indeed in some of its quarters several hundred habitable but almost deserted houses; and at every step the traveller treads upon portions of burned bricks, amongst which are often found fragments of porcelain, and even of marble. The most conspicuous buildings of fine baked brick which remain are the mosque, and a palace adjoining to it. The former is in a state of good preservation. Its windows, the work of India, are covered with bronze gratings skilfully manufactured, and the doors are handsomely and curiously carved. The palace is large, but in ruins, except a single pile of building in the centre, which is six stories in height, and has five rows of windows. The houses themselves are rarely of more than one story in height, and generally built of mud or straw. There is a bazaar, a wretched establishment, ill supplied with goods. Sennaar is situated in north latitude 13° 36′ 51″, and east longitude 33° 30′ 30″.

A great number of villages are scattered over the country, and especially along the banks of the rivers. One of these, called Misselemieh, situated some fifty miles below Sennaar, on the same river, is famous for its market, and is the resort of many merchants from Souakin, who bring cotton, spices, and perfumes to exchange for gold. One great staple of commerce in Sennaar is slaves, who are either taken in war, or stolen from Abyssinia, or sold from Darfur and other places where the inhabitants are born slaves. A considerable portion of the population of this country is free, but vast numbers are slaves. The natives are of two sorts, the free cultivators and the Mowelleds. The latter are a peculiar race; they are the descendants of slaves who for many generations have lived at large, and pay the masters to whom they belong, as locomotive property, a part of their monthly gains. Some of the great sheicks possess six or eight hundred of these Mowelleds, who may be sold like other slaves. The province below the town of Sennaar, and as far down as Berhee, is governed by a bey. The country above this town is divided into two commands, those who hold them having to pay an annual contribution to the pasha of Egypt, of so many ounces of gold, which, of course, is rigorously exacted from the inhabitants. The capital of one of these districts is called Goleh; it is said to be as large as Sennaar, and famous for its workers in iron. Reysenas is the name of another place of some consequence. (R. R. R.)

SENNERTUS, Daniel, an eminent physician, was born in 1572, at Breslau. In 1593 he was sent to Wittemberg, where he made great progress in philosophy and in physic. He visited the universities of Leipsig, Iena, Frankfort on the Oder, and Berlin; but he soon returned to Wittemberg, where he was promoted to the degree of doctor of physic, and soon afterwards to a professorship in the same faculty. He was the first who introduced the study of chemistry in to that university; and he gained a great reputation by his works and practice. He died of the plague at Wittemberg in 1637. By contradicting the ancients, he made himself enemies. He thought the seed of all living creatures animated, and that the soul of this seed produced organization.

He was accused of impiety for asserting that the souls of beasts are not material, for this was affirmed to be the same thing with asserting that they are immortal; but he rejected this consequence, as he well might do.

SENONES, in *Ancient Geography*, a people of Gallia Celtica, situated on the Sequana, to the south of the Parisii, near the confluence of the Jeauna or Yonne with the above-mentioned river. Their most considerable exploit was their invasion of Italy, and the taking and burning of Rome, as related under that article. This was done by a colony of them long before transported into Italy, and settled on the Adriatic. Their capital, Agendicum, in Gaul, was in the lower age called Senones, now Sens. In Italy the Senones extended themselves as far as the river Æsis, but were afterwards driven beyond the Rubicon, which became the boundary of Gallia Cisalpina.

SENRAB, a town of Hindustan, in the province of Allahabad, and district of Callinger, on the east side of the river Cane, twenty-four miles north from the town of Callinger. Long. 80. 25. E. Lat. 25. 18. N.

SENS, an arrondissement in the department of the Yonne, in France, which extends over 422 square miles, and comprehends six cantons, divided into ninety communes, with a population in 1836 of 61,036 inhabitants. The capital is the city of the same name, situated in a district rich in vines, on the river Yonne, where it is joined by the river Vannes. It has a cathedral of great antiquity and beauty, and pleasing walks on the banks of the river; and it contains 9095 inhabitants, who make cotton goods, hats, hosiery, and silks. Long. 3. 12. 16. E. Lat. 48. 11. 55. N.

SENSATION, in *Philosophy*, is the perception of external objects by means of the senses. See Metaphysics.

SENSE is a faculty of the soul, by which it perceives external objects by means of the impressions they make upon certain organs of the body. See Metaphysics.

Common Sense is a term that has been variously used both by ancient and by modern writers. With some it has been synonymous with public sense; with others it has denoted prudence; in certain instances it has been confounded with some of the powers of taste; and, accordingly, those who commit egregious blunders with regard to decorum, saying and doing what is offensive to their company, and inconsistent with their own character, have been charged with a defect in common sense. Some men are distinguished by an uncommon acuteness in discovering the characters of others; and this talent has been sometimes called common sense, similar to which is that use of the term which makes it to signify that experience and knowledge of life which is acquired by living in society. To this meaning Quintilian refers, when speaking of the advantages of a public education. "Sensum ipsum qui communis dicitur, ubi discet, cum se a congressu, qui non hominibus solum, sed mutis quoque animalibus naturalis est, segregarit? (Lib. i. cap. 2.)

But the term common sense has in modern times been employed to signify that power of the mind which perceives truth, or commands belief, not by progressive argumentation, but by an instantaneous, instinctive, and irresistible impulse, derived neither from education nor from habit, but from nature, acting independently of our will, whenever its object is presented according to an established law, and therefore called *sense;* and acting in a similar manner upon all, or at least upon a great majority of mankind, and therefore called *common sense.* See Metaphysics.

Moral Sense is a determination of the mind to be pleased with the contemplation of the affections, actions, or characters, of rational agents, which we call good or virtuous.

This moral sense of beauty in actions and affections may at first view appear strange. Some of our moralists themselves are offended at it in Lord Shaftesbury, as being accustomed to deduce every approbation or aversion from rational views of interest. It is certain that his lordship has carried the influence of the moral sense very far, and some of his followers have carried it farther. The advocates for the selfish system seem to drive their opinions to the opposite extreme; and we have elsewhere endeavoured to show that the truth lies between the contending parties. See Moral Philosophy.

SENSES, Pleasures and Pains of. The natural agreeableness, disagreeableness, and indifference of our sensations and perceptions, present to the mind an important and extensive field of inquiry; and on this subject we shall here make a few observations. All our senses have been certainly bestowed upon us for wise and beneficent purposes; and accordingly we find, that all of them, when properly cultivated, or exercised and improved, are capable of affording us pleasure. The senses of smell and of taste seem rather intended for the preservation of our animal existence, and in this point of view are properly an object of the natural history of man; whilst the other three seem to be more peculiarly intended for our mental improvement, and accordingly form the object of intellectual and of moral philosophy. And agreeably to this we know that we derive a great deal of useful knowledge, in an easy and simple manner, concerning the objects that surround us, in the early part of life, from all the senses, particularly from sight and touch, and this too without labour or study. But this is not the only purpose for which the senses were designed.

It being thus certain that the senses were bestowed upon us partly to preserve our animal existence, and partly for our mental improvement, it seems reasonable, even *a priori,* to expect that nature would attach some pleasure to such use and exercise of them as are calculated to promote these ends, and pain to the contrary; particularly in those instances in which she has left the management of them subject to our own control. And accordingly we cannot but observe what delight we derive from our senses, especially in the morning of life, by which it would seem that nature intended thus winningly to invite us to the proper exercise and improvement of them, and as it were unconsciously acquire much useful knowledge. It is this species of pleasure that supports and excites boys in the constant and often immoderate exercise of their organs of voluntary motion, the powers of which are thus increased and invigorated.

The exercise and improvement of the senses being subservient to our intellectual improvement, nature has also kindly attached much refined and rational pleasure to the mental exertions; so that we are thus seduced, as it were, to the cultivation of the various extraordinary powers and faculties of the mind.

It is evident that nature has given such organs and faculties to man, as are calculated not only to make him live, but also to render life agreeable. Here too we obtain a slight glimpse at least of some of the final causes of the pleasures of sense. But if it be asked how it happens that there are such wide diversities between our sensations, some being by nature very agreeable to all men, and some as disagreeable, whilst there are others so indifferent as to give neither pleasure nor pain, we must confess that we can give no satisfactory answer, to show how so many very different sensations are produced by various kinds of impressions made on certain organs of the body, and how all these different impressions excite such sensations as suggest not only corresponding perceptions and external qualities, but at the same time affect the mind with pleasure, pain, trouble, anxiety, or disgust. To be successful in these inquiries, we must presuppose some knowledge of the nature of the connection subsisting between the mind and the body, which there is reason to think is placed beyond the limits prescribed by nature to human research.

The pleasure or pain which constantly attends certain sensations is not uniform in degree, but varies considerably, not only in different individuals, but even in the same persons at different times. It is not thus with the sensations themselves. These are always constant and uniform. The same kind of impression, when the organs are sound, uniformly and invariably produces similar sensations; and these are as invariably followed by the perception of their own peculiar exciting causes. For any particular impression is never known to excite in the same person a new sensation, or the perceptions of an external object different from that which it previously suggested, excepting in cases of disease. And when it does rarely occur, as in those who cannot distinguish a particular colour, smell, or taste, from certain others, we uniformly attribute it to disease or malconformation. Were we not thus to have uniformly similar sensations and perceptions of external objects from similar impressions, the senses would not be at all subservient to our intellectual improvement, since, by giving different lessons concerning the same or similar objects at different times, they would render it impossible for us to be certain of any thing, or to benefit by experience.

The effects of custom, which are at all times so considerable and evident with respect both to the mind and the body, as in the case of particular organs or faculties much improved by attention and exercise, have little or no influence at all in interrupting or modifying this uniformity in our sensations and perceptions. For no sound or properly organized person will, either naturally or by custom, ever mistake hardness for softness, or red for green, or sweet for bitter. But the influence of custom in modifying the pains and pleasures of sense is well known and considerable. For a person who can most accurately distinguish sweetness from sourness, will, at the same time, either by particular conformation, or more frequently in consequence of use and habit, prefer wormwood or tobacco to honey.

But although we may despair of ever being able to discover the physical cause of the pleasures and pains of the senses, we may, however, advance a little by observing and registering particular facts. It is accordingly of use to remark, that every species of sensation, if its nature be otherwise unchanged, is agreeable or disagreeable in proportion to its strength or intenseness. For there is no sensation, however agreeable, that will not become disagreeable, and even intolerable, if it be immoderately intense. And, on the contrary, those which by their strength and nature are very troublesome, if rendered more mild and moderate, become not only tolerable, but agreeable. Thus, with respect to the senses, it would seem that pain and pleasure are only different degrees of the same feeling; and when we consider the great varieties of which the sensation, not only of different organs, but even of any one of them, is susceptible, and that each degree of these may be accompanied with pleasure or pain, more or less, we must conclude that the pains and pleasures of sense are capable of numberless modifications both in degree and in kind.

We frequently observe, that sensations which were at first agreeable, if often repeated, lose their relish, though the nature and strength of the impressions be the same; whilst others, from being at first very disagreeable, as the taste of tobacco and opium, become very pleasing, though the nature and strength of the impressions have suffered no change. For the explanation of such facts as these we must have recourse to the effects of custom. Thus, in both these opposite cases, the sensations, from being often repeated, lose part of the strength and of the novelty of their first impressions; and, with respect to the former instance, being unable to command the attention, they become in the course of time almost wholly, or altogether neglected, whilst in the latter case, from being very offensive, they become highly agreeable. But if it be asked why habit and custom produce these effects, and in what manner, we are unable to explain it farther, than by saying, since the fact is unquestionable, that such is the nature of the human constitution. Of the effects themselves, no man can entertain a doubt; and their causes, though at present unknown, may by time and inquiry be further developed and simplified. "The labyrinth," says Dr Reid, "may be too intricate, and the thread too fine, to be traced through all its windings; but if we stop where we can trace it no farther, and secure the ground we have gained, there is no harm done; a quicker eye may in time trace it farther."

These principles are capable of affording us still farther explanations. Why are new sensations always more agreeable, and variety so pleasing? Because they fix the attention more, and are not as yet blunted by frequent repetition or by habit. It is because some sensations lose their wonted effect by custom and by repetition, that we require stronger ones, or at least stronger impressions on the organs and nerves, to increase or continue our pleasures. It is also in consequence of their becoming less poignant through habit that we may neglect so many pleasures, which we hardly know to be such, till they have flown for ever; and it is because in the morning of life every thing has more novelty, and because habit has not destroyed their relish, that the pleasures of youth are much more intense than those of age. The degree of pleasure is similar to that which a blind man would feel on being made to see, or to that which a man would enjoy on suddenly acquiring a new sensitive faculty, although by long use and habit these pleasures are at present for the most part or wholly blotted away.

Although most sensations, when strong and lively enough to make themselves accurately and easily distinguished, generally please most, each in its own kind and manner; still, as there are different kinds of pleasure, different sensations may please the mind in various ways; and accordingly, it is not from the lustre of the midday sun, nor from the beautiful and lively appearance of all nature at noon, solely, that the eyes can derive pleasure, any more than grand musical sounds are the only things that please the ear. For we often contemplate with a very different and a very considerable degree of pleasure the sublime and awful scenes of nature, the twilight darkness of the shady grove, and even the gloomy horror of night itself. We listen with delight to the tempest shaking the forest, as well as to the gentle murmurs of the passing stream. There is even a time when nothing gives so much pleasure as darkness, silence, and the absence of all sensation.

Amidst the great variety of good and evil with which we are everywhere surrounded, it is a matter of the highest importance to be able to discern aright. This we should be incapable of doing were we not endowed with agreeable as well as painful sensations. These serve to direct our choice. Whatever contributes in any degree to our preservation, and to the improvement of our organs and faculties, is accompanied with pleasure; and, on the contrary, when we are threatened with danger, a painful sensation gives us the alarm. It is to the establishment of this law that we are indebted for the duration of our lives, the improved and vigorous state of our faculties, and the enjoyment of that small portion of happiness allotted to us by nature. "God," says a French writer, "having endowed man with various faculties, bodily as well as intellectual, in order to promote his happiness, also vouchsafes to conduct him to this noble end, not only by the deductions of reason, but also by the force of instinct and sensation, which are more powerful and efficacious principles. Thus nature, by a sensation of pain, instantaneously apprises us of what might prove hurtful to us; and, on the contrary, by an agreeable sensation, gently leads us to whatever may tend to the preservation of our existence, and to the perfect state of our faculties, these being the two points on which our happiness depends. Our faculties can neither be of use, nor display themselves, farther than as we exercise them. Motion or action is therefore so necessary to us, that without it we must inevitably sink into a deplorable state of insensibility and languor. On the other hand, as we are weak and limited creatures, all excessive and violent action would impair and destroy our organs; we must therefore use only moderate motion or exercise, since by these means the use or perfection of our faculties is reconciled with our chief interest, which is self-preservation. Now it is to this happy medium, we mean to a moderate exercise of our faculties, that the Author of our nature has so wisely annexed pleasure.

The pleasures of sense are thus confined within narrow limits; for they cannot be much increased without pain, or often repeated without losing their relish, at least in a great measure; nor can they be long continued, partly for the same reason, and because they exhaust the mind, or rather the nervous system. Hence we see that our animal appetites are confined within a narrow range, as is evident from the effects of excess in eating and drinking. All our sensitive powers are impaired; whilst, on the contrary, our intellectual powers are strengthened and improved by use and exercise. And in proportion as we indulge our sensitive powers, our desires of indulgence increase, whilst the pleasures which are the objects of these desires become regularly less poignant. These, indeed, are wise regulations of nature; for it would seem as if she intended to whisper gently to us in this way, by means of practical experience, that we are not born solely for the enjoyment of pleasure, at least not for that of the pleasures of the senses; for all of them, as we have already remarked, if much indulged, lead to listlessness and disgust, and sometimes to considerable pain. And indeed, just as pleasure passes thus readily into trouble and pain, so does the sudden cessation of pain, at least when this has been considerable, produce often extraordinary pleasure; so that we may here apply the beautiful allegory of Socrates, "that although pleasure and pain are contrary in their nature, and have their faces turned different ways, yet that Jupiter has tied them so together, that he who lays hold of the one draws the other along with it."

We have just said, that the sudden cessation of pain, at least when this has been considerable, produces often extraordinary pleasure. But this opinion seems to be denied by the author of an inquiry concerning taste. "Among the pleasures of sense," says Mr Knight, "more particularly among those belonging to touch, there is a certain class, which, though arising from negative causes, are nevertheless real and positive pleasures; as when we gradually sink from any violent or excessive degree of action or irritation into a state of tranquillity and repose. I say gradually, for if the transition be sudden and abrupt, it will not be pleasant; the pleasure arising from the inverted action of the nerves, and not from the utter cessation of action. From this inverted action arises the gratification which we receive from a cool breeze when the body has been excessively heated; or from the rocking of a cradle, or the gentle motion of a boat, or easy carriage, after having been fatigued with violent exercise. Such, too, is that which twilight, or the gloomy shade of a thicket, affords to the eye after it has been dazzled by the blaze of the mid-day sun; and such, likewise, is that which the ear receives from the gradual diminution of loudness of tone in music." That pleasure follows a gradual cessation of any violent action or irritation, we mean not to deny; but we are at a loss to comprehend how it follows that the transition from strong pain, if it be sudden and abrupt, will not be pleasant.

But although the pleasures of sense be thus limited, these limits are very different with respect to the different senses. Some of them are soon exhausted, and do not any longer distinguish well the objects that correspond to them; nor are they pleased with those objects which were at first very agreeable, and which they distinguish with sufficient accuracy; whilst others continue to perform their functions longer, and to enjoy a more continued pleasure. Thus the senses of smell and of taste are almost immediately satiated, the sense of hearing more slowly; but the sight is in this respect the last of all to be fatigued or satiated; whilst the pleasures that arise from the exercise of our mental faculties are by far the most durable of all. "Exercise of the mind is as necessary as that of the body to preserve our existence. The senses of other animals, being more quick than ours, are sufficient to direct them to follow what is agreeable to their nature, or to shun whatever is contrary thereto. But we are endowed with reason in order to supply the deficiency of our senses; and pleasure presents herself as an incitement to exercise, in order to keep the mind from a state of hurtful inactivity. Pleasure is not only the parent of sports and amusements, but also of arts and sciences; and as the whole universe is, as it were, forced by our industry to pay tribute to our wants and desires, we cannot but acknowledge our obligation to that law of nature which has annexed a degree of pleasure to whatever exercises without fatiguing the mind. The pleasure accompanying it is sometimes so great that it transports the very soul, so that she seems as it were disengaged from the body. We know what is recorded in history concerning Archimedes,[1] and several other geometricians, both ancient and modern. If we doubt the truth of such facts, we must at least acknowledge their probability, since we meet every day with a number of similar examples. When we see a chess-player so deeply immersed in thought as to be in a manner lost to his outward senses, should we not imagine him to be wholly engrossed with the care of his own private affairs, or of the public weal? But the object of all this profound meditation is the pleasure of exercising the mind by the movement of a piece of ivory. From this exercise of the mind also arises the pleasure we sometimes take in refined and delicate sentiments, which, after the manner of Virgil's shepherdess (*Et fugit ad salices, sed se cupit ante videri*), are sometimes artfully concealed, but so as to afford us the pleasure of discovering them."[2]

From some of the foregoing remarks we likewise see that nature points out to us the superiority and excellence of our mental faculties, thus suggesting to us that we ought to cultivate them most, as being our better and nobler part, to the cultivation of which that of our sensitive faculties should be merely subservient. But although our pleasures are thus by nature rendered in a great degree independent of ourselves, still we have it in our power to make them all more durable, by varying and mixing them with one another, or by interposing between those that are very agreeable others that are less pleasing, so as that no individual pleasure shall be in excess.

Besides the circumstances already noticed, there are others of a very different kind, which have also considerable influence on the pleasures of the senses; such as different conditions of the whole body, particularly of the nerves, or of certain organs or functions, to which functions some organs of sense, and perhaps even the sensation of these, are in a great measure subservient. This is one of the causes why many pleasures, which we cultivate with all our might, cannot be immortal. If a person be thirsty, spring-water is nectar to him; if hungry, any kind of food is agreeable, even the smell of food is grateful. To a man in a heat, or in a fever, cold is pleasing; and to one in a cold fit nothing is so agreeable as heat. To these same persons, at other times, so far are these things from being agreeable, that they are often disgusting. The most decided glutton cannot always relish a sumptuous feast.

---

[1] When Syracuse was taken by the Romans under Marcellus, Archimedes was in his study, so intent upon some geometrical problems, that he neither heard the clamour of the Romans, nor perceived that the city was taken. In this transport of study and contemplation, a soldier came on him with his drawn sword; Archimedes, on seeing him, besought him to hold his hand till he had finished the problem he was about. But the soldier, deaf to his entreaty, ran him through the body, although Marcellus, upon entering the city, had given orders that Archimedes should be spared.

[2] *Théorie des Sentiments Agréables.*

Besides the sensations excited by external objects, there are others also which cause pain and pleasure. If the action of the muscles be strong, easy, and cheerful, and not continued so as to fatigue us, it causes pleasure. On the contrary, when this action is attended with a sense of listlessness, lassitude, difficulty, and debility, it more or less causes pain. In fine, various states and affections of the mind, such as the exercise of memory, imagination, and judgment, nearly for similar reasons, are sometimes painful, at other times agreeable. "Animi affectus, qui modici grate excitant, vehementes, aut graves et diuturni, hujus pariter ac corporis vires frangunt; hominem interdum statim extinguunt, sæpius longa valetudine macerant. Somni etiam, quo ad exhaustas vires reficiendas egemus, excessus, vel defectus, et animo et corpori nocet." "Desidia, sive animi sive corporis, utriusque vires languescunt: nimia exercitatione haud minus læduntur. Statuit enim provida rerum parens, ut singularum partium, et universi corporis animique vires usu roborentur et acuantur; et huic iterum certos fines posuit: ita ut neque quem voluit natura usus impune omittatur, neque ultra modum intendatur." (*Conspectus Medicinæ.*)

"Of such sensations and feelings as are agreeable or disagreeable, we may remark," says Dr Reid, "that they differ much, not only in degree, but in kind and in dignity. Some belong to the animal part of our nature, and are common to us with the brutes; others belong to the rational and moral part. The first are more properly called sensations, the last feelings. The French word *sentiment* is common to both."

"The Author of nature, in the distribution of agreeable and painful feelings, hath wisely and benevolently consulted the good of the human species; and hath even shown us, by the same means, what tenor of conduct we ought to hold. For, first, the painful sensations of the animal kind are admonitions to avoid what would hurt us; and the agreeable sensations of this kind invite us to those actions that are necessary to the preservation of the individual, or of the kind. Secondly, by the same means nature invites us to moderate bodily exercise, and admonishes us to avoid idleness and inactivity on the one hand, and excessive labour and fatigue upon the other. Thirdly, the moderate exercise of all our rational powers gives us pleasure. Fourthly, every species of beauty is beheld with pleasure, and every species of deformity with disgust; and we shall find all that we denominate beautiful to be something estimable or useful in itself, or a sign of something that is estimable or useful. Fifthly, the benevolent affections are all accompanied with an agreeable feeling, the malevolent with the contrary. And, sixthly, the highest, the noblest, and most durable pleasure is that of doing well and acting the part that becomes us; and the most bitter and painful sentiment is the anguish and remorse of a guilty conscience." These observations with regard to the economy of nature in the distribution of our painful and agreeable sensations and feelings are so well illustrated by the elegant and judicious author of *Théorie des Sentiments Agréables*, that we deem it unnecessary to make any further remarks on this subject. A little reflection may satisfy us that the number and variety of our sensations and feelings are prodigious. For, to omit all those which accompany our appetites, passions, and affections, our moral sentiments and sentiments of taste, even our external senses, furnish a variety of sensations differing in kind, and almost in every kind an endless variety of degrees. Every variety we discern with regard to taste, smell, sound, colour, heat, and cold, and in the tangible qualities of bodies, is indicated by a sensation corresponding to it.

The most general and the most important division of our sensations and feelings is into the agreeable, the disagreeable, and the indifferent. Every thing we call pleasure, happiness, or enjoyment, on the one hand, and, on the other, every thing we call misery, pain, or uneasiness, is sensation or feeling. For no man can for the present be more happy, or more miserable, than he feels himself to be. He cannot be deceived with regard to the enjoyment or suffering of the present moment.

But, besides the sensations that are agreeable or disagreeable, there is still a greater number that are indifferent. To these we give so little attention that they have no name, and are immediately forgotten, as if they had never been; it even requires attention to the operations of our minds to be convinced of their existence. For this end we may observe, that to a good ear every human voice is distinguishable from all others. Some voices are pleasant, and some disagreeable; but the far greater part cannot be said to be the one or the other. The same thing may be said of other sounds, and no less of tastes, smells, and colours; and if we consider that our senses are in continual exercise while we are awake, that some sensation attends every object they present to us, and that familiar objects seldom raise any emotion pleasant or painful, we shall see reason, besides the agreeable and disagreeable, to admit a third class of sensations, that may be called indifferent. But these sensations that are indifferent are far from being useless. They serve as signs to distinguish things that differ; and the information we have concerning things external comes by these means. Thus, if a man had not a musical ear so as to receive pleasure from the harmony or melody of sounds, he would still find the sense of hearing of great utility. Though sounds gave him neither pleasure nor pain of themselves, they would give him much useful information; and the same may be said of the sensations which we have by all the other senses.

SENSIBLE NOTE, in *Music* (derived from the French term *note sensible*), means simply the note which ascends by a semitone to the tonic or key-note of any scale, major or minor. For example, in scale of C, B to C; or in scale of A, G♯ to A, and so on. (See MUSIC.) This note is one of the marked characteristics of modern European tonality.

SENSIBILITY is a nice and delicate perception of pleasure or pain, beauty or deformity. It is very nearly allied to taste, and, as far as it is natural, seems to depend upon the organization of the nervous system. It is capable, however, of cultivation, and is experienced in a much higher degree in civilized than in savage nations, and among persons liberally educated than among boors and illiterate mechanics. The man who has cultivated any of the fine arts has a much quicker and more exquisite perception of beauty and deformity in the execution of that art, than another of equal or even greater natural powers, who has but casually inspected its productions. He who has been long accustomed to that decorum of manners which characterizes the polite part of the world, perceives almost instantaneously the smallest deviation from it, and feels himself almost as much hurt by behaviour harmless in itself as by the grossest rudeness; and the man who has long proceeded steadily in the paths of virtue, and often painted to himself the deformity of vice, and the miseries of which it is productive, is more quickly alarmed at any deviation from rectitude than another who, though his life has been stained by no crime, has yet thought less upon the principles of virtue and consequences of vice.

Every thing which can be called sensibility, and is not born with man, may be resolved into association, and is to be regulated accordingly; for sensibilities may be acquired which are inimical to happiness and to the practice of virtue. The man is not to be envied who has so accustomed himself to the forms of polite address as to be hurt by the unaffected language and manners of the honest peasant with whom he may have occasion to transact business; nor is he likely to acquire much useful knowledge, who has so sedulously studied the beauties of composition, as to be unable to read without disgust a book of science or of history, of which the style comes not up to his standard of perfection. That sensibility which we either have from nature, or necessarily acquire, of the miseries of others, is of the greatest use when properly regulated, as it powerfully impels us to relieve their distress; but if it by any means become so exquisite as to make us shun the sight of misery, it counteracts the end for which it was implanted in our nature, and only deprives us of happiness, while it contributes nothing to the good of others. Indeed there is reason to believe that all such extreme sensibilities are selfish affectations, employed as apologies for withholding from the miserable that relief which it is in our power to give; for there is not a fact better established in the science of human nature, than that passive perceptions grow gradually weaker by repetition, while active habits daily acquire additional strength.

It is of great importance to a literary man to cultivate his taste, because it is the source of much elegant and refined pleasure; but there is a degree of fastidiousness which renders that pleasure impossible to be obtained, and is the certain indication of expiring letters. It is necessary to submit to the artificial rules of politeness, for they tend to promote the peace and harmony of society, and are sometimes a useful substitute for moral virtue; but he who with respect to them has so much sensibility as to be disgusted with all whose manners are not equally polished with his own, is a very troublesome member of society. It is every man's duty to cultivate his moral sensibilities so as to make them subservient to the purposes for which they were given to him; but if he either feel, or pretend to feel, the miseries of others to so exquisite a degree as to be unable to afford them the relief which they have a right to expect, his sensibilities are of no good tendency.

That the man of true sensibility has more pains and more pleasures than the callous wretch, is universally admitted, as well as that his enjoyments and sufferings are more exquisite in their kinds; and as no man lives for himself alone, no man will acknowledge his want of sensibility, or express a wish that his heart were callous. It is, however, a matter of some moment to distinguish real sensibilities from ridiculous affectations, those which tend to increase the sum of human happiness from such as have a contrary tendency; and to cultivate them all in such a manner as to make them answer the ends for which they were implanted in us by the beneficent Author of nature. This can be done only by watching over them as over other associations (see METAPHYSICS); for excessive sensibility, as it is not the gift of nature, is the bane of human happiness. "Too much tenderness," as Rousseau well observes, "proves the bitterest curse instead of the most fruitful blessing; vexation and disappointment are its certain consequences. The temperature of the air, the change of the seasons, the brilliancy of the sun, or thickness of the fogs, are so many moving springs to the unhappy possessor, and he becomes the wanton sport of their arbitration."

SENSITIVE PLANT. The sensitive plants are well known to possess a kind of motion, by which the leaves and stalks are contracted, and fall down on being slightly touched, or shaken with some degree of violence.

The contraction of the leaves and branches of the sensitive plant when touched is a very singular phenomena, and different hypotheses have been formed by botanists in order to explain it; but we are disposed to believe that these have generally been deduced rather from analogical reasoning than from a collection of facts and observations. We shall therefore give an account of all the important facts which we have been able to collect upon this curious subject; and then draw such conclusions as obviously result from them, without, however, attempting to support any old, or to establish a new, hypothesis.

First, it is difficult to touch the leaf of a healthy sensitive plant so delicately that it will not immediately collapse, the foliola or little leaves moving at their base till they come into contact, and then applying themselves close together. If the leaf be touched with a little more force, the opposite leaf will exhibit the same appearance. If a little more force be applied, the partial footstalks bend down towards the common footstalk from which they issue, making with it a more acute angle than before. If the touch be more violent still, all the leaves situated on the same side with the one that has been touched will instantly collapse, and the partial footstalk will approach the common footstalk to which it is attached, in the same manner as the partial footstalk of the leaf approaches the stem or branch from which it issues; so that the whole plant, from having its branches extended, will immediately appear like a weeping birch.

Secondly, these motions of the plant are performed by means of three distinct and sensible articulations; the first that of the foliola or lobes to the partial footstalk, the second that of the partial footstalk to the common one, and the third that of the common footstalk to the trunk; the primary motion of all which is, the closing of the leaf upon the partial footstalk, which is performed in a similar manner, and by a similar articulation. This, however, is much less visible than the others. These motions are wholly independent of one another, as may be proved by experiment. It appears, that if the partial footstalks are moved, and collapse toward the petioli, or these toward the trunk, the little leaves, whose motion is usually primary to these, should be affected also; yet experiment proves that it is possible to touch the footstalks in such a manner as to affect them only, and make them apply themselves to the trunk, while the leaves feel nothing of the touch. But this cannot be, unless the footstalks are so disposed as that they can fall to the trunk, without suffering their leaves to touch any part of the plant in their passage, because, if they do, they are immediately affected.

Thirdly, winds and heavy rains make the leaves of the sensitive plant contract and close; but no such effect is produced from slight showers.

Fourthly, at night, or when exposed to much cold in the day, the leaves meet and close in the same manner as when touched, folding their upper surfaces together, and in part over each other, like scales or tiles, so as to expose as little as possible of the upper surface to the air. The opposite sides of the leaves, or foliola, do not come close together in the night, for when touched they apply themselves closer together. Dr Darwin kept a sensitive plant in a dark place for some hours after daybreak; the leaves and footstalks were collapsed as in its most profound sleep, and on exposing it to the light, above twenty minutes passed before it was expanded.

Fifthly, in the month of August, a sensitive plant was carried in a pot out of its usual place into a dark cave; the motion that it received in the carriage shut up its leaves, and they did not open till twenty-four hours afterwards: at this time they became moderately open, but were afterwards subject to no changes at night or morning, but remained three days and nights with their leaves in the same moderately open state. At the end of this time they were ensitive Plant.

brought out again into the air, and there recovered their natural periodical motions, shutting every night, and opening every morning, as naturally and as strongly as if the plant had not been in this forced state; and while in the cave, it was observed to be very little less affected with the touch than when abroad in the open air.

Sixthly, the great heats of summer, when there is open sunshine at noon, affect the plant in some degree like cold, causing it to shut up its leaves a little, but never in any very great degree. The plant, however, is least of all affected about nine o'clock in the morning, and that is consequently the most proper time to make experiments on it. A branch of the sensitive plant cut off, and laid by, retains still its property of shutting up and opening in the morning for some days; and it holds it longer if kept with one end in water, than if left to dry more suddenly.

Seventhly, the leaves only of the sensitive plant shut up in the night, not the branches; and if it be touched at this time, the branches are affected in the same manner as in the day, shutting up, or approaching to the stalk or trunk, in the same way, and often with more force. It is of no consequence what the substance is with which the plant is touched, it answers alike to all; but there may be observed a little spot, distinguishable by its paler colour, in the articulations of its leaves, where the greatest and nicest sensibility is evidently placed.

Eighthly, Duhamel having observed, about the 15th of September, in moderate weather, the natural motion of a branch of a sensitive plant, remarked, that at nine in the morning it formed with the stem an angle of 100 degrees; at noon, 112 degrees; at three afternoon, it returned to 100, and after touching the branch, the angle was reduced to 90. Three quarters of an hour afterwards, it had mounted to 112; and at eight at night, it descended again, without being touched, to 90. The day after, in finer weather, the same branch, at eight in the morning, made an angle of 135 degrees with the stem; after being touched, the angle was diminished to 80; an hour after, it rose again to 135; being touched a second time, it descended again to 80; an hour and a half afterwards, it had risen to 145; and on being touched a third time, descended to 135, and remained in that position till five o'clock in the afternoon, when being touched a fourth time, it fell to 110.

Ninthly, the parts of the plants which have collapsed, afterwards unfold themselves, and return to their former expanded state. The time required for that purpose varies, according to the vigour of the plant, the season of the year, the hour of the day, the state of the atmosphere. Sometimes half an hour is requisite, sometimes only ten minutes. The order in which the parts recover themselves varies in like manner; sometimes it is the common footstalks, sometimes the rib to which the leaves are attached, and sometimes the leaves themselves are expanded, before the other parts have made any attempt to be reinstated in their former position.

Tenthly, if, without shaking the other smaller leaves, we cut off the half of a leaf or lobe belonging to the last pair, at the extremity or summit of a wing, the leaf cut, and its antagonist, that is to say, the first pair, begin to approach each other; then the second, and so on successively, till all the lesser leaves or lobes of that wing have collapsed in like manner. Frequently, after twelve or fifteen seconds, the lobes of the other wings, which were not immediately affected by the stroke, shut; whilst the stalk and its wing, beginning at the bottom, and proceeding in order to the top, gradually recover themselves. If, instead of one of the lesser extreme leaves, we cut off one belonging to the pair that is next the footstalk, its antagonist shuts, as do the other pairs successively, from the bottom to the top. If all the leaves of one side of a wing be cut off, the opposite leaves are not affected, but remain expanded. With some address, it is possible even to cut off a branch without hurting the leaves or making them fall. The common footstalk of the winged leaves being cut as far as three fourths of its diameter, all the parts which hang down collapse, but quickly recover without appearing to have suffered any considerable violence by the shock. An incision being made into one of the principal branches to the depth of one half the diameter, the branches situated between the section and the root will fall down; those above the incision remain as before, and the lesser leaves continue open; but this direction is soon destroyed, by cutting off one of the lobes at the extremity, as was observed above. Lastly, a whole wing being cut off with precaution near its insertion into the common footstalk, the other wings are not affected by it, and its own lobes do not shut. No motion ensues from piercing the branch with a needle or other sharp instrument.

Sensitive Plant.

Eleventhly, if the end of one of the leaves be burned with the flame of a candle, or by a burning-glass, or by touching it with hot iron, it closes up in a moment, and the opposite leaf does the same, and after that, the whole series of leaves on each side of the partial or little footstalk; then the footstalk itself; then the branch or common footstalk; all do the same, if the burning has been in a sufficient degree. This proves that there is a very nice communication between all the parts of the plant, by means of which the burning, which only is applied to the extremity of one leaf, diffuses its influence through every part of the shrub. If a drop of aquafortis be carefully laid upon a leaf of the sensitive plant, so as not to shake it in the least, the leaf does not begin to move till the acrid liquor corrodes the substance of it; but at that time, not only the particular leaf, but all the leaves placed on the same footstalk, close themselves up. The vapour of burning sulphur has also this effect on many leaves at once, according as they are more or less exposed to it; but a bottle of very acrid and sulphureous spirit of vitriol, placed under the branches unstopped, produces no such effect. Wetting the leaves with spirit of wine has been observed also to have no effect, nor the rubbing of oil of almonds over them; though this last application destroys many plants.

From the preceding experiments the following conclusions may be fairly drawn. First, the contraction of the parts of the sensitive plant is occasioned by an external force, and the contraction is in proportion to the force. Secondly, all bodies which can exert any force affect the sensitive plant; some by the touch or by agitation, as the wind or rain; some by chemical influence, as heat and cold. Thirdly, touching or agitating the plant produces a greater effect than an incision or cutting off a part, or by applying heat or cold.

Attempts have been made to explain these curious phenomena. Dr Darwin, in the notes to his Botanic Garden, lays it down as a principle, that "the sleep of animals consists in a suspension of voluntary motion; and as vegetables are subject to sleep as well as animals, there is reason to conclude," says he, "that the various action of closing their petals and foliage may be justly ascribed to a voluntary power; for without the faculty of volition sleep would not have been necessary to them." Whether this definition of sleep when applied to animals be just, we shall not inquire. But it is evident the supposed analogy between the sleep of animals and the sleep of plants has led Dr Darwin to admit this astonishing conclusion, that plants have volition. As volition presupposes a mind or soul, it were to be wished that he had given us some information concerning the nature of a vegetable soul, which can think and will. We suspect, however, that this vegetable soul will turn out to be a mere mechanical or chemical one; for it is affected by external forces uniformly in the same way, its volition is merely passive, and never makes any successful resistance against those causes by which it is influenced. All this is a mere abuse of words. The sleep of plants is a metaphorical expression, and has not the least resemblance to the sleep of animals. Plants are said to sleep when the flowers or leaves are contracted or folded together; but we never heard that there is any similar contraction in the body of an animal during sleep.

The fibres of vegetables have been compared with the muscles of animals, and the motions of the sensitive plant have been supposed to be the same with muscular motion. Between the fibres of vegetables and the muscles of animals, however, there is not the least similarity. If muscles be cut through, so as to be separated from the joints to which they are attached, their powers are completely destroyed; but this is not the case with vegetable fibres. The following ingenious experiment, which was communicated to us by a respectable member of the university of Edinburgh, is decisive on this subject. He selected a growing poppy at that period of its growth, before unfolding, when the head and neck are bent down almost double. He cut the stalk where it was curved half through on the under side, and half through at a small distance on the upper side, and half through in the middle point between the two sections, so that the ends of the fibres were separated from the stalk. Notwithstanding these several cuttings on the neck, the poppy raised its head, and assumed a more erect position. There is, therefore, a complete distinction between muscular motion and the motions of a plant; for no motion can take place in the limb of an animal when the muscles of that limb are cut.

In fine, we look upon all attempts to explain the motions of plants as absurd, and all reasoning from supposed analogy between animals and vegetables as the source of wild conjecture, and not of sound philosophy. We view the contraction and expansion of the sensitive plant in the same light as we do gravitation, chemical attraction, electricity, and magnetism, as a singular fact, the circumstances of which we may be fully acquainted with, but must despair of understanding its cause.

SENTENCE, in *Law*, a judgment passed in court by the judge in some process, either civil or criminal. See JUDGMENT.

SENTENCE, in *Grammar*, denotes a period, or a set of words comprehending perfect sense, or a sentiment of the mind. The business of pointing is to distinguish the several parts and members of sentences, so as to render the sense as clear, distinct, and full, as possible.

In every sentence there are two parts necessarily required; a noun for the subject, and a definite verb. Whatever is found more than these two, affects one of them, either immediately or by the intervention of some other, by which the first is affected.

Again, every sentence is either simple or compound. A simple sentence is that which consists of one single subject, and one finite verb. A compound sentence contains several subjects and finite verbs, either expressly or implicitly.

A simple sentence needs no point or distinction, but only a period to close it, as "A good man loves virtue for itself." In such a sentence, the several adjuncts affect either the subject or the verb in a different manner. Thus the word *good* expresses the quality of the subject, *virtue* the object of the action, and *for itself* the end thereof. Now none of these adjuncts can be separated from the rest of the sentence; for if one be, why should not all the rest? and if all be, the sentence will be minced into almost as many parts as there are words. But if several adjuncts be attributed in the same manner either to the subject or the verb, the sentence becomes compound, and is to be divided into parts.

In every compound sentence, as many subjects or as many finite verbs as there are, either expressed or implied, so many distinctions may there be. Thus, "My hopes, fears, joys, pains, all centre in you;" and thus, "*Catilina abiit, excessit, evasit, erupit.*" The reason of thus pointing is obvious; for as many subjects or finite verbs as there are in a sentence, so many members does it really contain. Whenever, therefore, there occurs more nouns than verbs, or contrariwise, they are to be conceived as equal; since, as every subject requires its verbs, so every verb requires its subject, with which it may agree, excepting, perhaps, in some figurative expressions.

SENTINEL, or SENTRY, in military affairs, is a private soldier placed in some post, to watch the approach of the enemy, to prevent surprises, or to stop such as would pass without orders or discovering who they are. They are placed before the arms of all guards, and at the tents and doors of general officers, colonels of regiments, &c.

SENTINEL Perdu, a soldier posted near an enemy, or in some dangerous position, where he is in hazard of being lost.

SENTINEL, *Great and Little*, are two islands in the Eastern Seas. The first is about ten miles in circumference, and is about twenty miles from the Greater Andaman. Long. 92. 40. E. Lat. 11. 36. N. The second is about eight miles from the Little Andaman. Long. 92. 23. E. Lat. 10. 59. N.

SEOUNY, a town of Hindustan, in the province of Gundwana, sixty-eight miles north by east from the city of Nagpoor. Long. 80. 3. E. Lat. 22. 4. N.

SEOUNY, a town of Hindustan, in the Mahratta territories, and province of Khandesh, seventy-three miles north by west from Ellichpoor. Long. 77. 1. E. Lat. 22. 21. N.

SEPARATISTS. This name has for some years been generally applied to a particular sect in these countries. It originated with a few Christians in Dublin, about the year 1803, who had their attention strongly directed to the principles of Christian fellowship. Convinced that the authority of the apostolic word was divine and unchangeable, not to be annulled or weakened by the lapse of time, by the customs of nations, or by the laws of earthly legislators, they set out in the attempt to return fully to the course marked out for Christians in the New Testament. There they perceived that all the first Christians in any place were connected together in the closest brotherhood, and that this connection, grounded on the apostolic gospel which they believed, was altogether regulated by the apostolic precepts, the commands of the divinely-commissioned ambassadors of Christ; and they also perceived that the same divine rule which regulated their fellowship in the gospel with each other, forbade them to maintain any religious fellowship with others. From the practice consequent on this, they received the name of *Separatists*, a designation since applied to them, by an act of parliament passed in the year 1833, for their relief in the matter of oaths. To give even a concise account of the tenets and practices by which they are distinguished from most other religionists in these countries, would require more space than could be allotted to this article; but among them the following principal may be noted. They hold that the only true God is made known to men exclusively in the gospel of his son Jesus Christ; that those alone who believe the divine testimony there revealed know the true God, whose distinguishing glory is displayed in the fullest harmony of perfect righteousness and perfect mercy, as the Saviour of sinful creatures, and the justifier of the ungodly, through the redemption that is in Christ Jesus, through the propitiation for sin which he made by his obedience unto death, and the divine acceptance of which is proved by his resurrection from the dead. They hold that forgiveness of all sin, acceptance in the sight of God, and eternal life, come to the guiltiest of sinners, as such, and are assured in the divine word to every one, without distinction, who believes the testimony concerning Jesus of Nazareth. They understand by the faith with which justification and eternal life are connected, nothing else but the belief of the things declared to all alike in the gospel; and by repentance, nothing but the change of mind which takes place on a sinner's believing the gospel. Both these they hold to be solely the work of God in his people; the Spirit of God working by his revealed word, in them to will and to do; and they acknowledge God to be the sole author and agent of every thing that is good, and that every thing which comes from the sinner himself, either before his conversion to God, or after it, is essentially evil. As a church they assemble on the first day of the week, as the memorial day of Christ's resurrection, to show forth his death, the only ground of their hope, by taking bread and wine, as the symbols of his body broken and his blood shed for the remission of sins; to join in the exercises of prayer and praise; to contribute to the necessities of the poor; to express their fraternal affection by saluting each other with an holy kiss; and to attend, as occasion requires, to the discipline appointed by the apostles for removing any evil which may appear among them. For a full account of their doctrines on baptism, the clerical character, and other subjects, see Essays and Correspondence of the late John Walker, London, 1838, two vols. 8vo.

SEPOURY, or Sipry, a town and fortress of Hindustan, province of Agra, and district of Gohud, taken by the British in 1781. It is eighteen miles south-west of Narwa.

SEPOYS, or Seapoys, natives of Hindustan serving in a military capacity under the European powers, and disciplined after the European manner.

SEPTEMBER, the ninth month of the year, consisting of thirty days. It took its name as being the seventh month from March, with which the Romans began their year.

SEPTENTRIO, in *Astronomy*, a constellation, usually called *ursa minor*.

In cosmography, the term *septentrio* denotes the same with north; and hence septentrional is applied to any thing belonging to the north.

SEPTICS are those substances which promote putrefaction, chiefly the calcareous earths, magnesia, and testaceous powders.

SEPTIZON, or Septizonium, in Roman antiquity, a celebrated mausoleum, built by Septimius Severus, in the tenth region of the city of Rome. It was so called from *septem* and *zona*, because it consisted of seven stories, each of which was surrounded by a row of columns.

SEPTUAGESIMA, in the calendar, denotes the third Sunday before Lent, or before Quadragesima Sunday. It is supposed by some to take its name from its being about seventy days before Easter.

SEPTUAGINT, the name given to a Greek version of the books of the Old Testament, from its being supposed to be the work of seventy-two Jews, who are usually called the seventy interpreters, because seventy is a round number.

The history of this version has been expressly written by Aristæas, an officer of the guards to Ptolemy Philadelphus. Ptolemy having erected a noble library at Alexandria, which he took care to fill with the most curious and valuable books from all parts of the world, was informed that the Jews had one containing the laws of Moses, and the history of that people; and being desirous of enriching his library with a Greek translation of it, he applied to the high priest of the Jews, and, to engage him to comply with his request, set at liberty all the Jews whom his father Ptolemy Soter had reduced to slavery. After such a step, he easily obtained what he desired. Eleazar the Jewish high priest sent back his ambassadors with an exact copy of the Mosaical law, written in letters of gold, and six elders of each tribe, in all seventy-two, who were received with marks of respect by the king, and then conducted into the isle of Pharos, where they were lodged in a house prepared for their reception, and supplied with every thing necessary. They set about the translation without loss of time, which they finished in seventy-two days; and the whole being read in presence of the king, he admired the profound wisdom of the laws of Moses, and sent back the deputies laden with presents, for themselves, the high priest, and the temple.

Aristobulus, who was tutor to Ptolemy Physcon, Philo, who lived in our Saviour's time, and was contemporary with the apostles, and Josephus, speak of this translation as made by seventy-two interpreters, in the reign of Ptolemy Philadelphus. All the Christian writers during the first fifteen centuries of the Christian era have admitted this account of the Septuagint as an undoubted fact. But since the Reformation, critics have boldly called it in question, because it was attended with circumstances which they think inconsistent, or at least improbable. Dupin has asked, why were seventy-two interpreters employed, since twelve would have been sufficient? Such an objection is trifling. We may as well ask, why did King James I. employ fifty-four translators in rendering the Bible into English, since Dupin thinks twelve would have been sufficient?

Prideaux objects, that the Septuagint is not written in the Jewish, but in the Alexandrian dialect; and could not therefore be the work of natives of Palestine. But these dialects were at that time probably the same, for both Jews and Alexandrians had received the Greek language from the Macedonians about fifty years before. Prideaux further contends, that all the books of the Old Testament could not be translated at the same time; for they exhibit great difference of style. To this it is sufficient to reply, that they were the work of seventy-two men, each of whom had separate portions assigned him.

The dean also urges, that Aristæas, Aristobulus, Philo, and Josephus, all directly tell us, that the law was translated, without mentioning any of the other sacred books. But nothing was more common among writers of the Jewish nation, than to give this name to the Scriptures as a whole. In the New Testament, law is used as synonymous with what we call the Old Testament. Besides, it is expressly said by Aristobulus, in a fragment quoted by Eusebius, that the whole Sacred Scripture was rightly translated through the means of Demetrius Phalereus, and by the command of Philadelphus. Josephus, indeed, says the learned dean, asserts, in the preface to his Antiquities, that the Jewish interpreters did not translate for Ptolemy the whole Scriptures, but the law only. Here the evidence is contradictory, and we have to determine whether Aristobulus or Josephus be most worthy of credit. We do not mean, however, to accuse either of forgery, but only to inquire which had the best opportunities of knowing the truth. Aristobulus was an Alexandrian Jew, tutor to an Egyptian king, and lived within a hundred years after the translation was made, and certainly had access to see it in the royal library. Josephus was a native of Palestine, and lived not until three hundred years or more after the translation was made, and many years after it was burned along with the whole library of Alexandria in the wars of Julius Cæsar. Supposing the veracity of these two writers equal, as we have no proof of the contrary, which of them ought we to consider as the best evidence? Aristobulus certainly. Prideaux, indeed, seems doubtful whether there was ever such a man; and Dr Hody supposes that the Commentaries on the five books of Moses, which bear the name of Aristobulus, were a forgery of the second century. To prove the existence of any human being, who lived two thousand years before us, and did not perform such works as no mere man ever performed, is a task which we are not disposed to undertake; and we believe that it would not be less difficult to prove that Philo and Josephus existed, than that such a person as Aristobulus did not exist. If the writings which have passed under his name were a forgery of the second century, it is surprising that they should have imposed upon Clemens Alexandrinus, who lived in the same century, and was a man of abilities, learning, and well acquainted with the writings of the ancients. Eusebius, too, quotes the Commentaries of Aristobulus. But, continues the learned dean, "Clemens Alexandrinus is the first author that mentions them. Now, had any such commentaries existed in the time of Philo and Josephus, they would surely have mentioned them." But is the circumstance of its not being quoted by every succeeding author a sufficient reason to disprove the authenticity of any book? Neither Philo nor Josephus undertook to give a list of preceding authors, and it was by no means the uniform practice of these times always to name the authors from whom they derived their information.

Prideaux further contends, that the sum which Ptolemy is said to have given to the interpreters is too great to be credible. If his computation were just, it certainly would be so. He makes it L.2,000,000 sterling; but other writers[1] reduce it to L.85,421, and some to L.56,947, neither of which is a sum so very extraordinary in so great and magnificent a prince as Philadelphus, who spent, according to Athenæus, not less than ten thousand talents on the furniture of one tent, which is six times more than what was spent in the whole of the embassy and translation, which amounted only to 1552 talents.

Prideaux says, "that what convicts the whole story of Aristæas of falsity is, that he makes Demetrius Phalereus to be the chief actor in it, and a great favourite of the king; whereas Philadelphus, as soon as his father was dead, cast him into prison, where he soon after died." But it may be replied, that Philadelphus reigned two years jointly with his father Lagus, and it is not said by Hermippus that Demetrius was out of favour with Philadelphus during his father's life. Now, if the Septuagint was translated in the beginning of the reign of Philadelphus, as Eusebius and Jerome think, the difficulty will be removed. Demetrius might have been librarian during the reign of Philadelphus, and yet imprisoned on the death of Lagus. Indeed, as the cause of Philadelphus's displeasure was the advice which Demetrius gave to his father, to prefer the sons of Arsinoë to the son of Bernice, he could scarcely show it till his father's death. The Septuagint translation might therefore be begun while Philadelphus reigned jointly with his father, but not be finished till after his father's death.

Besides the objections which have been considered, there is only one that deserves notice. The ancient Christians not only differ from one another concerning the time in which Aristobulus lived, but even contradict themselves in different parts of their works. Sometimes they tell us he dedicated his book to Ptolemy Philometer; at other times they say it was addressed to Philadelphus and his father. Sometimes they make him the same person who is mentioned in second Maccabees, and sometimes one of the seventy-two interpreters a hundred and fifty-two years before. It is difficult to explain how authors fall into such inconsistencies, but it is probably occasioned by their quoting from memory. This was certainly the practice of almost all the early Christian writers, and sometimes of the apostles themselves. Mistakes were therefore inevitable. Josephus has varied in the circumstances of the same event, in his Antiquities and Wars of the Jews, probably from the same cause; but we do not hence conclude, that every circumstance of such a relation is entirely false. In the account of the Marquis of Argyll's death in the reign of Charles II. we have a very remarkable contradiction. Lord Clarendon relates that he was condemned to be hanged, which was performed the same day. On the contrary, Burnet, Wodrow, Heath, and Echard, concur in stating that he was beheaded; and that he was condemned upon the Saturday, and executed upon the Monday.[2] But was any reader of English history ever sceptical enough to raise from hence a question, whether the Marquis of Argyll was executed or not? Yet this ought to be left in uncertainty, according to the way of reasoning in which the facts respecting the translation of the Septuagint are attempted to be disproved.

Such are the objections which Prideaux has raised against the common account of the Septuagint translation, and such are the answers which may be given to them. We have chosen to support that opinion which is sanctioned by historical evidence, in preference to the conjectures of modern critics, however ingenious; being persuaded that there are many things recorded in history, which, though perfectly true, yet, from our imperfect knowledge of the concomitant circumstances, may, at a distant period, seem liable to objections. To those who require positive evidence, it may be stated thus. Aristæas, Aristobulus, Philo, and Josephus, assure us that the law was translated. Taking the law in the more restricted sense, we have at least sufficient authority to assert that the Pentateuch was rendered into Greek under Ptolemy Philadelphus. Aristobulus affirms, that the whole Scriptures were translated by the seventy-two. Josephus confines their labours to the books of Moses. He therefore who cannot determine to which of the two the greater respect is due, may suspend his opinion. It is certain, however, that many of the other books were translated before the age of our Saviour; for they are quoted both by him and by his apostles; and, perhaps, by a minute examination of ancient authors, in the same way that Dr Lardner has examined the Christian fathers to prove the antiquity of the New Testament, the precise period in which the whole books of the Septuagint were composed might, with considerable accuracy, be ascertained.

For four hundred years this translation was in high estimation with the Jews. It was read in their synagogues in preference to the Hebrew, not only in those places where Greek was the common language, but in many synagogues of Jerusalem and Judæa. But when they saw that it was equally valued by the Christians, they became jealous of it; and at length, in the second century, Aquila, an apostate Christian, attempted to substitute another Greek translation in its place. In this work he was careful to give the ancient prophecies concerning the Messiah a different turn from the Septuagint, that they might not be applicable to Christ. In the same design he was followed by Symmachus and Theodotion, who also, as St Jerome informs us, wrote out of hatred to Christianity.

In the mean time, the Septuagint, from the ignorance, boldness, and carelessness of transcribers, became full of errors. To correct these, Origen published a new edition in the beginning of the third century, in which he placed the translations of Aquila, Symmachus, and Theodotion. This edition was called *Tetrapla*, the translations being arranged opposite to one another in four columns. He also added one column, containing the Hebrew text in Hebrew letters, and another exhibiting it in Greek. In a second he published two additional Greek versions, one of which was found at Nicopolis, and the other at Jericho. This was called the *Hexapla*. By comparing so many translations, Origen endeavoured to form a correct copy of the Scriptures. Where they all agreed, he considered them as right. The passages which he found in the Septuagint, but not in the Hebrew text, he marked with an obelisk; what he found in the Hebrew, but not in the Septuagint, he marked with an asterisk. St Jerome says, that the additions which Origen made to the Septuagint, and marked with an asterisk, were taken from Theodotion. From this valuable work of Origen the version of the Septuagint was transcribed in a separate volume, with the asterisks and obelisks for the use of the churches; and from this circumstance the great work itself was neglected and lost.

---

[1] Blair's Lectures on the Canon.

[2] *Biographia Britannica.*

About the year 300, two new editions of the Septuagint were published; the one by Hesychius, an Egyptian bishop, and the other by Lucian, a presbyter of Antioch. But as these authors did not mark with any note of distinction the alterations which they had made, their edition does not possess the advantages of Origen's.

The best edition of the Septuagint is that of Dr Grabe, which was published in the beginning of the last century. He had access to two manuscripts nearly of equal antiquity, the one found in the Vatican library at Rome, the other in the royal library at St James's, which was presented to Charles I. by Cyril, patriarch of Alexandria, and hence is commonly called the Alexandrian Manuscript. Anxious to discover which of these was according to the edition of Origen, Dr Grabe collected the fragments of the Hexapla, and found that they agreed with the Alexandrian Manuscript, but not with the Vatican where it differed with the other. Hence he concluded that the Alexandrian Manuscript was taken from the edition of Origen. By comparing the quotations from Scripture in the works of Athanasius and St Cyril, who were patriarchs of Alexandria at the time St Jerome says Hesychius's edition of the Septuagint was used there, with the Vatican manuscript, he found they agreed so well that he justly inferred that the manuscript was taken from the edition of Hesychius.

This version was in use to the time of our blessed Saviour, and is that out of which most of the citations in the New Testament from the Old are taken. It was also the ordinary and canonical translation made use of by the Christian church in the earliest ages; and it still subsists in the churches both of the east and the west.

(Those who desire a more particular account of the Septuagint translation may consult Hody *De Bibliorum Textibus*, Prideaux's Connections, Owen's Inquiry into the Septuagint Version, Blair's Lectures on the Canon, and Michaelis's Introduction to the New Testament, last edition.)

Septuagint *Chronology*, the chronology which is formed from the dates and periods of time mentioned in the Septuagint translation of the Old Testament. It reckons 1500 years more from the creation to Abraham than does the Hebrew Bible. Dr Kennicot, in the dissertation prefixed to his Hebrew Bible, has shown it to be very probable that the chronology of the Hebrew Scriptures, since the period just mentioned, was corrupted by the Jews between the years 175 and 200, and that the chronology of the Septuagint is more agreeable to the truth. It is a fact, that during the second and third centuries the Hebrew Scriptures were almost entirely in the hands of the Jews, while the Septuagint was confined to the Christians. The Jews had therefore a very favourable opportunity for this corruption. The following is the reason which is given by oriental writers. It being a very ancient tradition that the Messiah was to come in the sixth chiliad, because he was to come in the last days, the contrivance was to shorten the age of the world from about 5500 to 3760, and thence to prove that Jesus could not be the Messiah. Dr Kennicot adds, that some Hebrew copies having the larger chronology were extant till the time of Eusebius, and some till the year 700.

SEPULCHRE, a tomb or place destined for the interment of the dead. This term is chiefly used in speaking of the burying-places of the ancients, those of the moderns being usually called tombs.

Sepulchres were held sacred and inviolable, and the care taken of them has always been held a religious duty, grounded on the fear of God, and the belief of the soul's immortality. Those who have searched or violated them have been thought odious by all nations, and were always severely punished.

The Egyptians called sepulchres "eternal houses," in contradistinction to their ordinary houses or palaces, which they called "inns," on account of the short stay in the one in comparison with their long abode in the other.

Regular Canons of St Sepulchre, a religious order, formerly instituted at Jerusalem in honour of the holy sepulchre, or the tomb of Jesus Christ.

Many of these canons were brought from the Holy Land into Europe, particularly into France, by Louis the Younger; into Poland, by Jaxa, a Polish gentleman; into Flanders, by the counts of that country; and many also came into England. This order was, however, suppressed by Pope Innocent VIII., who gave its revenues and effects to that of our Lady of Bethlem; and this also becoming extinct, they were bestowed on the knights of St John of Jerusalem. But the suppression did not take effect in Poland, where they still subsist, as also in several provinces of Germany. These canons follow the rule of St Augustin.

Knights of the Holy Sepulchre, a military order, established in Palestine about the year 1114.

The knights of this order in Flanders, in 1558, chose Philip II. king of Spain for their master, and afterwards his son; but the grand-master of the order of Malta prevailed on him to resign; and when afterwards the Duke de Nevers assumed the same quality in France, the same grand-master, by his interest and credit, procured a like renunciation by him, and a confirmation of the union of this order to that of Malta.

SEQUANI, a people anciently forming a part of Gallia Celtica, but annexed to Belgica by Augustus, separated from the Helvetii by Mount Jura, with the Rhine on the east, bordering on the Ædui and Segustiani to the south, and Lingones to the west; now Franche Comté.

SEQUESTRATION, in *Common Law*, is setting aside the thing in controversy from the possession of both the parties that contend for it. In this sense it is either voluntary, as when done by the consent of the parties; or necessary, as where it is done by the judge, of his own authority, whether the parties are inclined or the reverse.

Sequestration is also used for the act of gathering the fruits of a benefice void, to the use of the next incumbent.

Sometimes a benefice is kept under sequestration for many years, when it is of so small value that no clergyman fit to serve the cure will be at the charge of taking it by institution; in which case the sequestration is committed either to the curate alone, or to the curate and churchwardens jointly. Sometimes the profits of a living in controversy, either by the consent of the parties, or by the judge's authority, are sequestered, and placed for safety in a third hand, till the suit is determined, a minister being appointed by the judge to serve the cure, and allowed a certain salary out of the profits. Sometimes the profits of a living are sequestered for neglect of duty, for dilapidations, or for satisfying the debts of the incumbent.

SEQUIN, a gold coin, struck at Venice, and in several parts of the grand signior's dominions. In Turkey it is called *dahob*, or piece of gold, and, according to Volney, is in value about 6s. 3d. sterling. It varies, however, considerably in its value in different countries. At Venice it is equal to about 9s. 2d. sterling.

SERA, a town of the south of India, in the province of Mysore, and capital of a district of the same name. The climate is subject to drought, and there seldom falls as much rain as is required to raise a full crop. Rice is the most beneficial product, and in favourable years the greater part of the watered land is sown with it; but in dry seasons coarser grains are sown. The trade carried on is to the nizam's country, the Mahrattas, and Bednore, Seringapatam, and Bangalore, and the article of exportation is the dried kernel of the cocoa-nut. This place, which was first conquered by the Bejapoor Mohammedan government in 1644, was afterwards the seat of an independent principality, which was at its greatest prosperity under Delawar Khan, immediately before it was conquered by Hyder, at which time the natives assert it to have contained 50,000 houses. It afterwards suffered many calamities from Tippoo and the Mahrattas, and now contains scarcely 300 houses; but it is fast reviving. In the district of Sera, all the villages were strongly fortified; and frequent famines took place, when the inhabitants were in the practice of plundering each other to support life. The defence of the villages against plunderers was conducted, not by fire-arms, but by throwing stones, in which the inhabitants are very dexterous. The town is eighty four miles north from Seringapatam. Long. 76. 55. E. Lat. 13. 37. N.

SERAGLIO, formed from the Persian word *seraw*, or Turkish word *serai*, which signifies a house, is commonly used to express the house or palace of a prince. In this sense it is frequently used at Constantinople, where the houses of foreign ambassadors are called seraglios. But it is commonly used by way of eminence for the palace of the grand signior at Constantinople, where he keeps his court, where his concubines are lodged, and where the youth are trained up for the chief posts of the empire.

SERAI, a building on the high road, or in large cities, in India, erected for the accommodation of travellers.

SERAMPEI, a country or district in the interior of the island of Sumatra. It has on the north and north-west Korinchi; on the east, south-east, and south, Pakalang, Jambee, and Sungei-tenang; and on the west and south-west, a river and chain of high mountains. It comprehends fifteen fortified and independent villages.

SERAMPOOR, a town in the province of Bengal, and district of Birbhoom, 107 miles west from Moorshedabad. Long. 80. 24. E. Lat. 24. 6. N.

SERAMPORE, a town of Bengal, belonging to the Danes, situated on the west side of the Hooghly river, about twelve miles above Calcutta. Serampore has a pleasing appearance viewed from the river, the houses being tolerably well built, of brick, and whitened; they have flat roofs, with balconies and Venetian windows, though few of them are more than two stories in height. There is a handsome church, and a battery of twelve pieces of cannon, chiefly for saluting, for the town is without fortifications. The trade which the Calcutta merchants carried on during the war, under cover of the Calcutta flag, was very profitable to the Danes who were settled here. The trade which it now carries on with Europe and China is but trifling. It is chiefly supported by missionaries; and insolvent debtors from Calcutta found here an asylum, from whence they could set their creditors at defiance. The missionaries have here established a printing-press, and printed the Scriptures in various dialects. During the short war with the Danes it was taken possession of by the British; but it was soon afterwards restored. Long. 88. 26. E. Lat. 22. 45. N.

SERANGANI Isles, a group of small islands in the Eastern Seas, about five leagues south of Magindanao, and between the fifth and sixth degrees of north latitude. The largest island is called Hummock Isle, about thirty miles in circumference. The next in size is about twenty-five miles in circumference; and there is another of somewhat inferior dimensions. This island, which is the most westerly, is very high and of a conical form, and its northern coast is very bold. It is fertile and well cultivated, and produces most of the tropical fruits, also rice, sugar-canes, pine-apples, mangoes, sour oranges, limes, jacks, plantains, cocoa-nuts, sago, sweet potatoes, tobacco, &c. The ships that pass, trade with the inhabitants for poultry, goats, and other refreshments; and one principal article of trade is bees' wax. There is a great demand among the natives for white or printed cottons, such as loose gowns or jackets, coloured handkerchiefs, knives, razors, and bar-iron. The inhabitants are, like almost all the islanders in the Eastern Seas, addicted to piracy; and they have canoes, and also larger boats, armed with small brass cannon, with which they carry on this trade of plunder. The Dutch claimed the sovereignty over these islands, which, however, they seldom exercised.

SERAPH, or Seraphim, spirits of the highest rank in the hierarchy of angels, who are so called from their being supposed to be the most inflamed with divine love, by their nearer and more immediate attendance at the throne of God, and to communicate their fervour to the remoter and inferior orders. Seraphim is the Hebrew plural of seraph.

SERAPION, a physician of Alexandria. He and Philinus of the isle of Cos were both scholars of Herophilus, and were founders of the empirical sect, which happened about 287 before Christ.

SERAPIS, in *Mythology*, an Egyptian deity, who was worshipped under various names and attributes, as the tutelary god of Egypt in general, and as the patron of several of their principal cities. Tacitus informs us, that he was worshipped as a kind of universal deity, that represented Æsculapius, Osiris, Jupiter, and Pluto. He was sometimes taken for Jupiter Ammon, the Sun, and Neptune; and the honours that were rendered to him at Alexandria were more solemn and extraordinary than those of any other place.

Plutarch and Clemens of Alexandria, as well as Tacitus,[1] inform us, that whilst the first Ptolemy was employed in fortifying Alexandria with walls, and adorning it with temples and stately buildings, there appeared to him in his sleep a young man of extraordinary beauty, of a stature more than human, admonishing him to despatch into Pontus some of his most trusty friends, to bring from thence his statue; assuring him that the city and kingdom which possessed it should prove happy, glorious, and powerful. The young man having thus spoken, disappeared, mounting up into heaven in a blaze of fire.

Ptolemy discovered his vision to the priests; but finding them ignorant of Pontus, he had recourse to an Athenian, who informed him that near Sinope, a city of Pontus, there was a temple much resorted to by the natives, which was consecrated to Pluto, where he had a statue, near which stood that of a woman. Ptolemy neglecting the injunctions of the apparition, it again appeared to him in a menacing attitude; and the king immediately despatched ambassadors to the Serapian monarch, loaded with presents. The king of Sinope consented, but his subjects opposed the removal of the statue. The god, however, of his own accord, as we are informed, conveyed himself to the ambassadors' ship, and in three days landed in Alexandria. The statue of Serapis was erected in one of the suburbs of the city, where a magnificent temple was afterwards reared.

The statue of Serapis, according to Macrobius, was of a human form, with a basket or bushel on his head, signifying plenty; his right hand leaned on the head of a serpent, whose body was wound round a figure with three heads, of a dog, a lion, and a wolf; and in his left hand he held a measure of a cubit in length, as if it were to take the height of the waters of the Nile. The figure of Serapis is found on many ancient medals.

The famous temple of Serapis at Alexandria was destroyed by order of Theodosius; and the celebrated statue of this deity was broken in pieces, and its limbs carried first in triumph by the Christians through the city, and then thrown into a fierce fire kindled for that purpose in the amphitheatre. As the Egyptians ascribed the overflowing of the Nile, to which was owing the fertility of their country, to the benign influence of their god Serapis, they concluded, that now he was destroyed, the river would no longer overflow, and that a general famine would ensue; but when they observed, on the contrary, that the Nile swelled to a

ereek || erge.

greater height than had been known in the memory of man, and thereby produced plenty of all kinds of provisions, many of the pagans, renouncing the worship of idols, adored the God of the Christians.

SEREEK, a town of Persia, in the province of Mekran, about four miles from the coast, near the entrance of the Persian Gulf. It contains a large mud fort and 600 huts, and is 105 miles north of Jask.

SERENADE (*Serenata*), a concert of instrumental or of vocal music, or of both, given under the windows of a house, generally after nightfall; and common in Italy and Spain as a mark of amatory respect. The *Notturno* is of the same kind.

SERENUS SAMMONICUS, a celebrated physician in the reigns of the Emperors Severus and Caracalla, about the year 200. He wrote several treatises on history and the works of nature; but there is only one of them extant, which is a very indifferent poem on the Remedies of Diseases. He was murdered at a festival by the order of Caracalla. He had a library that contained sixty-two thousand volumes, which Quintus Serenus Sammonicus, his son, gave to Gordian the younger, to whom he was preceptor.

SERES, a people of the Farther Asia, bounded on the west by Scythia without Imaus, on the north and east by Terra Incognita, and on the south by India beyond the Ganges. According to these limits, their country answers nearly to Cathay or Northern China. Mela places them between the Indi and Scythæ, and perhaps beyond the Indi, if we distinguish them from the Sinæ. The ancients commend them for their cotton manufactures, different from the produce of the bombyces or silk-worms, called *seres* by the Greeks; and hence *serica* means silk.

SERES, or *Sirus*, a city of European Turkey, in the province of Rumelia, and the circle of the Bay of Contessa. It stands on a fine plain watered by the rivers Egrifu and Stromza; but it is considered as unhealthy. It is surrounded with walls, which are in a neglected state. It contains ten mosques, several Greek and Armenian churches, and about thirty thousand inhabitants. It is the chief market for cotton wool, which is extensively cultivated on the fertile plains around it. It has also a considerable trade in rice, tobacco, and fruits of all kinds.

SERGE, a woollen quilted stuff, manufactured on a loom with four treddles, after the manner of rateens, and other stuffs that have the whale. The goodness of serges is known by the quilting, as that of cloths by the spinning. Of serges there are various kinds, denominated either from their different qualities or from the places where they are wrought. The most considerable is the London serge, which is now highly valued abroad.

The method of making the London serge we shall now describe. For wool, the longest is chosen for the warp, and the shortest for the woof. Before either kind is used, it is first scoured, by putting it into a copper of liquor somewhat more than lukewarm, composed of three parts of water and one of urine. After being kept long enough in it for the liquor to dissolve and take off the grease, it is stirred briskly about with a wooden peel, taken out of the liquor, drained, washed in a running water, and dried in the shade; it is then beaten with sticks on a wooden rack to drive out the coarser dust and filth, and picked clean with the hands. Thus far prepared, it is greased with oil of olives, and the longest part, destined for the warp, is combed with large combs heated in a small furnace. To clear off the oil again, the wool is put in a liquor composed of hot water with soap melted in it; whence being taken out, wrung, and dried, it is spun on the wheel.

As to the shorter wool, intended for the woof, it is only carded on the knee with small cards, and then spun on the wheel, without being scoured of its oil. It must be remarked, that the thread for the warp is always to be spun much finer, and better twisted, than that of the woof. The wool both for the warp and the woof being spun, and the thread divided into skains, that of the woof is put on spools fit for the cavity or eye of the shuttle, and that for the warp is wound on a kind of wooden bobbins to fit it for warping. When warped, it is stiffened with a kind of size, of which that made of the shreds of parchment is considered as the best, and when dry it is put on the loom.

Sergeant.

When mounted on the loom, the workman, raising and lowering the threads, which are passed through a reed, by means of four treddles placed underneath the loom, which he makes to act transversely, equally, and alternately, one after another, with his feet, in proportion as the threads are raised and lowered, throws the shuttle across from one side to the other; and, each time that the shuttle is thrown, and the thread of the woof is crossed between those of the warp, strikes it with the frame to which the reed is fastened; through those teeth the threads of the warp pass; and this stroke he repeats twice or thrice, or even more, till he judges the crossing of the serge sufficiently close. Thus he proceeds till the warp is all filled with woof.

The serge, now taken off the loom, is carried to the fuller, who scours it in the trough of his mill with a kind of fat earth called fuller's earth, first purged of all stones and filth. After three or four hours' scouring, the fuller's earth is washed out in fair water, brought by little and little into the trough, out of which it is taken when all the earth is cleared; then, with a kind of iron pincers, all the knots, ends, and straws sticking out on the surface on either side are pulled off; and then it is returned into the fulling trough, where it is worked with water somewhat more than lukewarm, with soap dissolved in it, for nearly two hours. It is next washed till such time as the water becomes quite clear, and there be no signs of soap left, when it is taken out of the trough, the knots again pulled off, and put on the tenter to dry, taking care as fast as it dries to stretch it out both in length and breadth, till it be brought to its just dimensions. When well dried, it is taken off the tenter, and dyed, shorn, and pressed.

SERGEANT, or SERJEANT, *at Law*, or of the Coif, is the highest degree, taken at the common law, as that of doctor is of the civil law; and as these are supposed to be the most learned and experienced in the practice of the courts, there is one court appointed for them to plead in by themselves, which is the Common Pleas, where the common law of England is most strictly observed. But they are not restricted from pleading in any other court, where the judges, who cannot have that honour till they have taken the degree of sergeant-at-law, call them brothers.

Sergean-tat-Arms, or *Mace*, an officer appointed to attend the person of the king, to arrest traitors and such persons of quality as offend, and to attend the lord high steward when sitting in judgment on a traitor.

There are four other sergeants-at-arms, created in the same manner; one, who attends the lord chancellor; a second, the lord treasurer; a third, the speaker of the House of Commons; and a fourth, the lord mayor of London on solemn occasions.

Common Sergeant, an officer in the city of London, who attends the lord mayor and court of aldermen on court days, and is in council with them on all occasions, within and without the precincts or liberties of the city. He takes care of orphans' estates, either by taking account of them, or by signing their indentures, before these pass the lord mayor and court of aldermen; and he likewise lets and manages the orphan estates, according to his judgment, to the best advantage.

Sergeant, in *War*, is an uncommissioned officer in a company of foot or troop of dragoons, armed with an halbert, and appointed to see discipline observed, to teach the soldiers the exercise of their arms, and to order, straighten, and form their ranks and files. He receives the orders from the adjutant, which he communicates to his officers. Each company has generally two sergeants.

SERGEANTY (*serjeantia*) signifies, in *Law*, a service that cannot be due by a tenant to any lord but the king; and this is either grand sergeanty or petit. The first is a tenure by which the one holds his lands of the king by such services as he ought to do in person to the king at his coronation, and may also concern matters military, or services of honour in peace. Petit sergeanty is where a man holds lands of the king to furnish him yearly with some small thing towards his wars, and in effect payable as rent. Though all tenures are turned into soccage by the 12th Car. II. cap. 24, yet the honorary services of grand-sergeanty still remain, being excepted in that statute.

SERIES, in general, denotes a continual succession of things in the same order, and having the same relation or connection with each other. In this sense we say, a series of emperors, kings, bishops, and the like.

In natural history, a series is used for an order or subdivision of some class of natural bodies; comprehending all such as are distinguished from the other bodies of that class, by certain characters which they possess in common, and which the rest of the bodies of that cast have not.

SERIES.

(1.) Series, in *Arithmetic* or *Algebra*, a rank or progression of quantities which succeed one another according to some determinate law. For example, the numbers

$$3, 5, 7, 9, 11, 13, 15, \text{ \&c.}$$

constitute a series, the law of which is, that each term exceeds that before it by a given number, viz. 2. Again, the numbers

$$3, 6, 12, 24, 48, 96, 192, \text{ \&c.}$$

constitute a series of a different kind, each term being the product of the term before it, and the given number 2.

(2.) As the law according to which the terms of a series are formed may be infinitely varied, there may be innumerable kinds of series. We shall enumerate a few of the most common.

1. *Arithmetical Series.* The general form of a series of this kind is

$$a,\ a+d,\ a+2d,\ a+3d,\ a+4d, \text{ \&c.}$$

and its law is, that the difference between any two adjacent terms is the same quantity, viz. d. The first of the two preceding examples is a series of this nature.

2. *Geometrical Series.* Its general form is

$$a,\ ar,\ ar^2,\ ar^3,\ ar^4, \text{ \&c.}$$

In this kind of series each term is the product of that which precedes it and a constant number r, which is called the common ratio of the terms. The second of the above examples is a particular case of a geometrical series.

3. *Harmonic Series* is that in which the first of any three of its consecutive terms is to the third, as the difference between the first and second to the difference between the second and third; hence we readily find, that putting a and b for its first two terms, its general form will be

$$a,\ b,\ \frac{ab}{2a-b},\ \frac{ab}{3a-2b},\ \frac{ab}{4a-3b}, \text{ \&c.}$$

If we suppose $a=1$ and $b=\frac{1}{2}$, we get

$$1, \tfrac{1}{2}, \tfrac{1}{3}, \tfrac{1}{4}, \tfrac{1}{5}, \tfrac{1}{6}, \text{ \&c.}$$

as a particular example of a harmonic series.

4. *Recurring Series.* Let its terms be denoted by

$$A, B, C, D, E, F, \text{ \&c.}$$

Then we shall form a recurring series if, m and n being put for given quantities, we take

$$C = mA + nB, \qquad E = mC + nD,$$
$$D = mB + nC, \qquad F = mD + nE.$$

For example, let us suppose $A=1$, $B=2x$, $m=4x^2$, $n=3x$; then $C=10x^2$, $D=38x^3$, $E=154x^4$, $F=614x^5$, so that the first six terms of the series are

$$1, 2x, 10x^2, 38x^3, 154x^4, 614x^5.$$

We have here supposed each term to be formed from the two which come immediately before it; but the name *recurring series* is given to every one in which the terms are formed in like manner from some assigned number of the terms which precede that sought. Thus, putting, as before, A, B, C, D, &c. for the terms of the series, and m, n, p, q, for given quantities, we shall have another recurring series, if we suppose them so related that

$$mA + nB + pC + qD = 0,$$
$$mB + nC + pD + qE = 0,$$
$$mC + nD + pE + qF = 0.$$

The two series of quantities sin. a, sin. $2a$, sin. $3a$, &c. and cos. a, cos. $2a$, cos. $3a$, &c. are both recurring, as is manifest from the law which connects the quantities one with another. (See Algebra, § 251.)

(3.) As in general it is the sum of the terms of a series which is the object of investigation, it is usual to connect them by the sign + or —, and to apply the name *series* to the expression thus formed. Accordingly,

$$1+3+5+7+9\cdots+\{1+2(n-1)\}$$

(where n denotes the number of terms) is called an arithmetical series; and in like manner

$$1+\tfrac{1}{2}+\tfrac{1}{4}+\tfrac{1}{8}\cdots+\frac{1}{2^{n-1}}$$

is a geometrical series.

(4.) A series may either consist of a definite number of terms, or their number may be supposed greater than any that can be assigned, and in this case the series is said to be *infinite.* The number of terms of a series may be infinite, and yet their sum finite. This is true, for example, of the series

$$\tfrac{1}{2}+\tfrac{1}{4}+\tfrac{1}{8}+\tfrac{1}{16}+, \text{ \&c.}$$

which is equivalent to unity, or 1.

(5.) We have already treated of several branches of the doctrine of series in the articles Algebra, Fluxions, and Logarithms; and, in particular, we have given four different methods for expanding a quantity into a series, viz.

1. By *Division* or *Evolution.*
2. By *the Method of Indeterminate Co-efficients.*
3. By *the Binomial Theorem.* (Algebra, sect. xvii.)
4. By *Taylor's Theorem.* (Fluxions, § 28.)

We shall here treat briefly of another branch of the theory, namely, how to find the sum of any proposed number of terms of certain series, or the sum of their terms continued *ad infinitum*, when that sum is finite.

(6.) There is a great analogy between the terms of a series and the ordinates of a curve which are supposed to stand upon the axis at equal distances from one another, the first ordinate reckoned from the extremity of the axis being analogous to the first term of the series, the second ordinate to the second term, and so on. From this analogy it follows immediately, that like as the nature of a curve is indicated by an equation expressing the value of an indefinite ordinate in terms of its corresponding abscissa, so also the nature of a series may be shown by an equation which shall express the relation between any term, and the number that denotes the place or order of that term in the series. In conformity to this method, putting the symbols $T_{(1)}$, $T_{(2)}$, $T_{(3)}$, &c., to denote the terms of any series whatever, we may express it generally thus,—

$$T_{(1)} + T_{(2)} + T_{(3)} \cdots + T_{(v)},$$

where the characters (1), (2), are meant to denote the place or order of the terms to which they are joined (the first term being supposed to have the place 1, the second term the place 2, and so on), and (v) is put for any indefinite number.

The nature of the arithmetical series

$$a + (a + d) + (a + 2d) + (a + 3d) +, \&c.$$

will be defined by the equation

$$T_{(v)} = a + (v - 1)d;$$

and, in like manner, the nature of the geometrical series

$$a + ar + ar^2 + ar^3 +, \&c.$$

will be expressed by the equation

$$T_{(v)} = ar^{v-1}.$$

(7.) As the expression for the value of the indefinite term $T_{(v)}$ becomes identical with all the terms of the series in succession, by substituting the numbers 1, 2, 3, &c. one after another, for v, that expression is called the *general term* of the series. In the series

$$a + b + \frac{ab}{2a - b} + \frac{ab}{3a - 2b} + \frac{ab}{4a - 3b} +, \&c.$$

the general term is evidently $\frac{ab}{(v-1)a - (v-2)b}$.

(8.) We shall investigate the sum of any number of terms of such series as have their general terms expressed by any one of the following algebraic functions.

$$v, \frac{v(v+1)}{1 \cdot 2}, \frac{v(v+1)(v+2)}{1 \cdot 2 \cdot 3}, \frac{v(v+1)(v+2)(v+3)}{1 \cdot 2 \cdot 3}, \&c.$$

Problem I. It is proposed to find the sum of n terms of the series of which the general term is the first function.

By putting 1, 2, 3, &c. to n successively for v, it appears that the series to be summed is

$$1 + 2 + 3 + 4 \cdots + n.$$

Now, as $v = \frac{v(v+1)}{2} - \frac{(v-1)v}{2}$, we have, by putting in this formula 1, 2, 3, $\cdots$ to n successively, for v,

$$1 = \frac{1 \cdot 2}{2} - 0,$$

$$2 = \frac{2 \cdot 3}{2} - \frac{1 \cdot 2}{2},$$

$$3 = \frac{3 \cdot 4}{2} - \frac{2 \cdot 3}{2},$$

$$4 = \frac{4 \cdot 5}{2} - \frac{3 \cdot 4}{2},$$

$$\cdots\cdot$$

$$n - 1 = \frac{(n-1)n}{2} - \frac{(n-2)(n-1)}{2},$$

$$n = \frac{n(n+1)}{2} - \frac{(n-1)n}{2}.$$

Let the sum of the quantities on each side of the sign = be now taken; then, observing that each of the fractions on the right-hand side, with the exception of $\frac{n(n+1)}{1 \cdot 2}$, occurs twice, once with the sign +, and again with the sign —, by which it happens that their aggregate is = 0, it is evident that we have

$$1 + 2 + 3 + 4 \cdots + n = \frac{n(n+1)}{1 \cdot 2}.$$

Prob. II. It is proposed to sum n terms of the series having for its general term the second function

$$\frac{v(v+1)}{1 \cdot 2}.$$

This series, by substituting 1, 2, 3, &c. successively for v, is found to be

$$\frac{1 \cdot 2}{1 \cdot 2} + \frac{2 \cdot 3}{1 \cdot 2} + \frac{3 \cdot 4}{1 \cdot 2} \cdots + \frac{n(n+1)}{1 \cdot 2}.$$

We now, following the mode of proceeding employed in last problem, put the expression $\frac{v(v+1)}{1 \cdot 2}$ under this form,

$$\frac{v(v+1)(v+2)}{1 \cdot 2 \cdot 3} - \frac{(v-1)v(v+1)}{1 \cdot 2 \cdot 3},$$

to which it is evidently equivalent, and, substituting 1, 2, 3, &c. successively for v, find

$$\frac{1 \cdot 2}{1 \cdot 2} = \frac{1 \cdot 2 \cdot 3}{1 \cdot 2 \cdot 3} - 0,$$

$$\frac{2 \cdot 3}{1 \cdot 2} = \frac{2 \cdot 3 \cdot 4}{1 \cdot 2 \cdot 3} - \frac{1 \cdot 2 \cdot 3}{1 \cdot 2 \cdot 3},$$

$$\frac{3 \cdot 4}{1 \cdot 2} = \frac{3 \cdot 4 \cdot 5}{1 \cdot 2 \cdot 3} - \frac{2 \cdot 3 \cdot 4}{1 \cdot 2 \cdot 3},$$

$$\frac{4 \cdot 5}{1 \cdot 2} = \frac{4 \cdot 5 \cdot 6}{1 \cdot 2 \cdot 3} - \frac{3 \cdot 4 \cdot 5}{1 \cdot 2 \cdot 3}$$

$$\cdots\cdots$$

$$\frac{n(n+1)}{1 \cdot 2} = \frac{n(n+1)(n+2)}{1 \cdot 2 \cdot 3} - \frac{(n-1)n(n+1)}{1 \cdot 2 \cdot 3}.$$

In this problem, as in the former, it appears that each quantity on the right side of the equations, except $\frac{n(n+1)(n+2)}{1 \cdot 2 \cdot 3}$, occurs twice, and with contrary signs; therefore, taking the aggregate of the terms on each side, we have

$$\frac{1 \cdot 2}{1 \cdot 2} + \frac{2 \cdot 3}{1 \cdot 2} + \frac{3 \cdot 4}{1 \cdot 2} + \frac{4 \cdot 5}{1 \cdot 2} \cdots + \frac{n(n+1)}{1 \cdot 2}$$
$$= \frac{n(n+1)(n+2)}{1 \cdot 2 \cdot 3}.$$

(9.) It will be obvious, by a little attention to the solutions of these two problems, that in each, the terms of the series to be summed are the differences betwixt the adjacent terms of another series, namely, that which has for its general term the function next in order to the general term of the series under consideration; that is, the terms of the series whose general term is v, are the differences betwixt those of the series having $\frac{v(v+1)}{1 \cdot 2}$ for its general term; and again, the terms of this last are the differences of the terms of the series having $\frac{v(v+1)(v+2)}{1 \cdot 2 \cdot 3}$ for its general term. Now, as the sum of the differences of any series of quantities whatever which begins with 0 must necessarily be the last term of that series,[1] it follows that the sum of all the terms of each of the series we have considered must be equal to the last term of the next following series; and this term is necessarily the expression formed by substituting n for v in its general term, that is, the sum of the series $1 + 2 + 3 \cdots + n$, which has v for its general term, is $\frac{n(n+1)}{1 \cdot 2}$; and the sum of the series

---

[1] For example, let the quantities be $0, a, b, c, d$; then it is manifest that $(a - 0) + (b - a) + (c - b) + (d - c) = d$.

$$\frac{1\cdot 2}{1\cdot 2}+\frac{2\cdot 3}{1\cdot 2}+\frac{3\cdot 4}{1\cdot 2}\cdots + + \frac{n(n+1)}{1\cdot 2}$$

$$\text{is } \frac{n(n+1)(n+2)}{1\cdot 2\cdot 3}$$

The next series, which has $\frac{v(v+1)(v+2)}{1\cdot 2\cdot 3}$ for its general term, as well as all that succeed, will be found to have the very same property, as may be proved as follows. Let p denote any term of the series of natural numbers 1, 2, 3, &c. Then, because

$$1=\frac{v+p}{p+1}-\frac{v-1}{p+1},$$

if we multiply these equals by the product of all the factors $v, \frac{v+1}{2}\ \frac{v+2}{3}$, &c. to $\frac{v+p-1}{p}$, we get

$$\frac{v(v+1)(v+2)\cdots(v+p-1)}{1\cdot 2\cdot 3\cdots p}$$

$$=\begin{cases}\dfrac{v(v+1)(v+2)\cdots(v+p)}{1\cdot 2\cdot 3\cdots(p+1)}\\ -\dfrac{(v-1)v(v+1)\cdots(v+p-1)}{1\cdot 2\cdot 3\cdots(p+1)}.\end{cases}$$

Now, if in this identical equation we substitute the numbers 1, 2, 3, &c. to n successively, for v, the results obtained from its first member

$$\frac{v(v+1)(v+2)\cdots(v+p-1)}{1\cdot 2\cdot 3\cdots p},$$

will be a series having this function for its general term, and the terms of which will evidently be the difference between the terms of another series having the first part of the second member of the equation, viz.

$$\frac{v(v+1)(v+2)\cdots(v+p)}{1\cdot 2\cdot 3\cdots(p+1)},$$

for its general term: Hence it will happen, as in the two foregoing problems, that the sum of all the terms of the former series will be equal to the last term of the latter; which conclusion may be expressed in the form of a theorem, as follows:

THEOREM. *The sum of* n *terms of a series having for its general term the function*

$$\frac{v(v+1)(v+2)\cdots(v+p-1)}{1\cdot 2\cdot 3\cdots p},$$

is equal to

$$\frac{n(n+1)(n+2)\cdots(n+p)}{1\cdot 2\cdot 3\cdots(p+1)}.$$

Or, setting aside the denominators of the terms, we may express the theorem thus: *The sum of* n *terms of a series, having for its general term the expression*

$$v(v+1)(v+2)\cdots(v+p-1),$$

is equal to

$$\frac{n(n+1)(n+2)\cdots(n+p)}{p+1}.$$

We shall give a few particular cases of this formula.

I. $1+2+3+4\cdots+n=\frac{n(n+1)}{2}.$

II. $1\cdot 2+2\cdot 3+3\cdot 4+4\cdot 5\cdots+n(n+1)$

$$=\frac{n(n+1)(n+2)}{3}.$$

III. $1\cdot 2\cdot 3+2\cdot 3\cdot 4+3\cdot 4\cdot 5\cdots+n(n+1)(n+2)$

$$=\frac{n(n+1)(n+2)(n+3)}{4}.$$

(10.) By means of the above general theorem, we may find the sum of any number of terms of a series composed of the powers of the terms of an arithmetical progression, the general term of which will, in the simplest case, be v^p, p being a given number. The manner of doing this will appear from the following problems.

PROB. III. It is proposed to find the sum of n terms of the series of squares $1+4+9+16+25+$, &c. or $1^2+2^2+3^2+4^2+5^2+$, &c.

The general term of this series being v^2, we put it under this form, $v(v+1)-v$; hence we get, by substituting 1, 2, 3, &c. for v,

$$1^2=1\cdot 2-1,$$
$$2^2=2\cdot 3-2,$$
$$3^2=3\cdot 4-3,$$
$$4^2=4\cdot 5-4,$$
$$\cdots$$
$$n^2=n(n+1)-n.$$

Therefore, adding, we find

$$1^2+2^2+3^2+4^2\cdots+n^2$$
$$=\begin{cases}1\cdot 2+2\cdot 3+3\cdot 4+4\cdot 5\cdots+n(n+1)\\ -(1+2+3+4\cdots+n).\end{cases}$$

But by the general theorem (9.)

$$1\cdot 2+2\cdot 3+3\cdot 4\cdots+n(n+1)=\frac{n(n+1)(n+2)}{3},$$

$$\text{and } 1+2+3+4\cdots+n=\frac{n(n+1)}{2};$$

$$\text{therefore } 1^2+2^2+3^2+4^2\cdots+n^2$$
$$=\frac{n(n+1)(n+2)}{3}-\frac{n(n+1)}{2}$$
$$=\frac{n(n+1)(2n+1)}{6}.$$

We might have arrived at the same conclusion by considering, that since v^2, the general term of the series, is equivalent to $v(v+1)-v$, the series must be the difference between two others, one having $v(v+1)$ and the other v for its general term; for the sake of perspicuity, however, we have put down the terms of all the three series.

PROB. IV. It is proposed to find the sum of n terms of the series

$$1^3+2^3+3^3+4^3+5^3+, \&c.$$

The general term in this case is v^3; now, to transform this function, so as to deduce the sum of the series from the general theorem, we assume

$$v^3=v(v+1)(v+2)+Av(v+1)+Bv,$$

where A and B denote quantities which are to have such values as shall render the two sides of the equation identical, whatever be the value of v. Taking now the product of the factors, we have

$$v^3=v^3+(A+3)v^2+(A+B+2)v;$$

therefore, by the theory of indeterminate co-efficients (ALGEBRA, § 159),

$$A+3=0,\ A+B+2=0:$$

hence we find $A=-3$, $B=-A-2=1$; thus it appears that, v being any number whatever,

$$v^3=v(v+1)(v+2)-3v(v+1)+v.$$

Now, let S denote the sum of n terms of the series under consideration, which has v^3 for its general term, and put P, Q, R for the like sums of the three series whose general terms are the functions $v(v+1)(v+2)$, $v(v+1)$, and v respectively; then it is evident that $S=P-3Q+R$. But by the theorem (9.)

$$P=\frac{n(n+1)(n+2)(n+3)}{4},$$

$$Q=\frac{n(n+1)(n+2)}{3},$$

$$R=\frac{n(n+1)}{2};$$

$$\text{therefore } S = \frac{n(n+1)(n+2)(n+3)}{4}$$
$$-n(n+1)(n+2) + \frac{n(n+1)}{2},$$

and, by proper reduction,

$$S = 1^3 + 2^3 + 3^3 + 4^3 \cdots + n^3 = \frac{n^2(n+1)^2}{4},$$

Corollary. We have found (Prob. I.) that

$$1 + 2 + 3 + 4 \cdots + n = \frac{n(n+1)}{2};$$

therefore, comparing this with the result just now obtained, it is evident that

$$(1 + 2 + 3 + 4 \cdots + n)^2 = 1^3 + 2^3 + 3^3 + 4^3 \cdots + n^3.$$

This is a very curious and elegant property of numbers.

(11.) It is manifest that, by the mode of proceeding employed in last problem, we may investigate the sum of n terms of the series

$$1^m + 2^m + 3^m + 4^m +, \&c.$$

m being any whole positive number whatever; and indeed in the very same way we may find the sum of any number of terms of a series whose general term is

$$a + bv + cv^2 + dv^3 +, \&c.$$

where a and b, &c. denote given numbers; namely, by transforming it into a function of the form

$$A + Bv + Cv(v+1) + Dv(v+1)(v+2) +, \&c.$$

where A, B, and C, &c. denote constant quantities. Our limits, however, will not allow us to go into particulars.

(12.) The next class of series we shall consider, comprehends such as may be formed by the successive substitution of a, $a+1$, $a+2$, &c. (a being put for any given quantity whatever) in the series of functions

$$\frac{1}{v(v+1)}, \frac{1}{v(v+1)(v+2)}, \frac{1}{v(v+1)(v+2)(v+3)}, \&c.$$

We shall begin with the first of these.

Prob. V. It is proposed to find the sum of n terms of the series

$$\frac{1}{a(a+1)} + \frac{1}{(a+1)(a+2)} + \frac{1}{(a+2)(a+3)} +, \&c.$$

which is formed by substituting a, $a+1$, $a+2$, &c. successively for v in the general term $\frac{1}{v(v+1)}$.

Whatever be the value of v, we have

$$\frac{1}{v(v+1)} = \frac{1}{v} - \frac{1}{v+1};$$

therefore, proceding as in the foregoing problems, we get

$$\frac{1}{a(a+1)} = \frac{1}{a} - \frac{1}{a+1},$$
$$\frac{1}{(a+1)(a+2)} = \frac{1}{a+1} - \frac{1}{a+2},$$
$$\frac{1}{(a+2)(a+3)} = \frac{1}{a+2} - \frac{1}{a+3},$$
$$\cdots\cdots$$
$$\frac{1}{(a+n-2)(a+n-1)} = \frac{1}{a+n-2} - \frac{1}{a+n-1},$$
$$\frac{1}{(a+n-1)(a+n)} = \frac{1}{a+n-1} - \frac{1}{a+n}.$$

Here it is evident that the terms of the series to be summed are the differences betwixt every two adjoining terms of this other series,

$$\frac{1}{a} + \frac{1}{a+1} + \frac{1}{a+2} + \frac{1}{a+3} \cdots + \frac{1}{a+n};$$

hence it immediately follows, that the sum of all the terms of the former is the difference between the two extreme terms of the latter; that is,

$$\frac{1}{a(a+1)} + \frac{1}{(a+1)(a+2)} \cdots + \frac{1}{(a+n-1)(a+n)}$$
$$= \frac{1}{a} - \frac{1}{a+n}.$$

If we suppose the series to be continued *ad infinitum*, then, as n will be indefinitely great, and $\frac{1}{a+n}$ indefinitely small, the sum will be simply $\frac{1}{a}$; or, in other words, the fraction $\frac{1}{a}$ is a limit to the sum of the series.

Prob. VI. Let it be required to find the sum of n terms of this series,

$$\frac{1}{a(a+1)(a+2)} + \frac{1}{(a+1)(a+2)(a+3)}$$
$$+ \frac{1}{(a+2)(a+3)(a+4)} +, \&c.;$$

the general term in this case being $\frac{1}{v(v+1)(v+2)}$.

Because $\frac{2}{v(v+2)} = \frac{1}{v} - \frac{1}{v+2}$, therefore, multiplying by $\frac{1}{2(v+1)}$, we have

$$\frac{1}{v(v+1)(v+2)} = \tfrac{1}{2}\left\{\frac{1}{v(v+1)} - \frac{1}{(v+1)(v+2)}\right\};$$

and hence, by substituting a, $a+1$, $a+2$, &c. successively for v,

$$\frac{1}{a(a+1)(a+2)} = \tfrac{1}{2}\left\{\frac{1}{a(a+1)} - \frac{1}{(a+1)(a+2)}\right\},$$
$$\frac{1}{(a+1)(a+2)(a+3)} = \tfrac{1}{2}\left\{\frac{1}{(a+1)(a+2)}\right.$$
$$\left.-\frac{1}{(a+2)(a+3)}\right\},$$
$$\frac{1}{(a+2)(a+3)(a+4)} = \tfrac{1}{2}\left\{\frac{1}{(a+2)(a+3)}\right.$$
$$\left.-\frac{1}{(a+3)(a+4)}\right\},$$
$$\cdots\cdots$$
$$\frac{1}{(a+n-1)(a+n)(a+n+1)}$$
$$= \tfrac{1}{2}\left\{\frac{1}{(a+n-1)(a+n)} - \frac{1}{(a+n)(a+n+1)}\right\}.$$

Hence it appears that the terms of the series to be summed are the halves of the differences of the terms of the series

$$\frac{1}{a(a+1)} + \frac{1}{(a+1)(a+2)} + \frac{1}{(a+2)(a+3)} \cdots$$
$$+ \frac{1}{(a+n)(a+n+1)};$$

consequently, the sum of all the terms of the former is half the difference between the extreme terms of the latter, or is =

$$\tfrac{1}{2}\left\{\frac{1}{a(a+1)} - \frac{1}{(a+n)(a+n+1)}\right\}.$$

(13.) From these two particular cases it is easy to see how we may sum the series when the general term is

$$\frac{1}{v(v+1)(v+2)\ldots(v+p)},$$

p being any whole number whatever: for since

$$\frac{p}{v(v+p)}=\frac{1}{v}-\frac{1}{v+p},$$

therefore, multiplying the denominators by all the factors which are intermediate between v and $v+p$, we have

$$\frac{p}{v\,(v+1)\,(v+2)\ldots(v+p)}$$

$$=\frac{1}{v\,(v+1)\,(v+2)\ldots(v+p-1)}$$

$$-\frac{1}{(v+1)\,(v+2)\,(v+3)\ldots(v+p)}.$$

Now the latter side of this equation is a general expression for the difference between any two adjacent terms of a series whose general term is

$$\frac{1}{v\,(v+1)\,(v+2)\ldots(v+p-1)},$$

therefore the difference between the first and last terms of this series must be the sum of the series whose general term is the function on the other side of the equation, viz.

$$\frac{p}{v\,(v+1)\,(v+2)\ldots(v+p)},$$

Hence we have the following very general theorem.

THEOREM. *Let* a *denote any number whatever, and let* 1, 2, 3 . . . p *be a series of numbers, each of which exceeds that before it by unity; the sum of* n *terms of a series formed by substituting the numbers* a, a + 1, a + 2, &c. *to* a + n — 1 *successively for* v *in the function*

$$\frac{1}{v\,(v+1)\,(v+2)\ldots(v+p)}$$

is equal to

$$\frac{1}{p}\left\{\begin{array}{l}\dfrac{1}{a\,(a+1)\,(a+2)\ldots(a+p-1)}\\[2ex] -\dfrac{1}{(a+n)(a+n+1)(a+n+2)\ldots+(a+n+p-1)}.\end{array}\right.$$

COROLLARY. *The same series continued* ad infinitum *is equal to*

$$\frac{1}{p}\cdot\frac{1}{a\,(a+1)\,(a+2)\ldots(a+p-1)}.$$

(14.) We shall now give examples of the application of this theorem.

Example 1. Required the sum of n terms of the series

$$\frac{1}{2\cdot3\cdot4\cdot5}+\frac{1}{3\cdot4\cdot5\cdot6}+\frac{1}{4\cdot5\cdot6\cdot7}+,\ \&c.$$

The terms of this series are evidently produced by the successive substitution of the numbers 2 3, 4, 5, &c. for v in the function

$$\frac{1}{v\,(v+1)\,(v+2)\,(v+3)};$$

therefore, comparing this expression with the general formula, we have $a=2$, $p=3$, and the sum required

$$=\tfrac{1}{3}\left\{\frac{1}{2\cdot3\cdot4}-\frac{1}{(2+n)\,(3+n)\,(4+n)}\right\}.$$

Ex. 2. Required the sum of the series

$$\frac{1}{1\cdot4\cdot7}+\frac{1}{4\cdot7\cdot10}+\frac{1}{7\cdot10\cdot13}+\frac{1}{10\cdot13\cdot16}+,\ \&c.$$

continued *ad infinitum.*

By a little attention it will appear that its terms are produced by the substitution of the numbers $\frac{1}{3}$, $1\frac{1}{3}$, $2\frac{1}{3}$, &c. successively for v in the function

$$\frac{1}{3v\,(3v+3)\,(3v+6)}=\frac{1}{27v\,(v+1)\,(v+2)}.$$

In this case, $a=\frac{1}{3}$, $p=2$, therefore the sum is

$$\frac{1}{2}\times\frac{1}{27}\times\frac{1}{\frac{1}{3}\times1\frac{1}{3}}=\frac{1}{24}.$$

(15.) When the function from which the series is derived has not the very form required in the theorem, it may be brought to that form by employing suitable transformations, as in the two following examples.

Ex. 3. It is proposed to find the sum of the series

$$\frac{1}{1\cdot4}+\frac{1}{2\cdot5}+\frac{1}{3\cdot6}+\frac{1}{4\cdot7}+,\ \&c.$$

continued *ad infinitum.*

This series is evidently formed by the substitution of the numbers 1, 2, 3, &c. successively for v in the function $\frac{1}{v\,(v+3)}$. This expression, however, does not in its present form agree with the general formula, because the factors $v+1$, $v+2$ are wanting; therefore, to transform it, we multiply its numerator and denominator by $(v+1)$ $(v+2)$, and it becomes

$$\frac{(v+1)\,(v+2)}{v\,(v+1)\,(v+2)\,(v+3)}.$$

We next assume its numerator

$$(v+1)(v+2)=\mathrm{A}\,(v+2)(v+3)+\mathrm{B}\,(v+3)+\mathrm{C},$$

and by multiplying get

$$v^2+3v+2=\mathrm{A}v^2+(5\mathrm{A}+\mathrm{B})\,v+(6\mathrm{A}+3\mathrm{B}+\mathrm{C});$$

therefore, that v may be indeterminate, we must make

$$\mathrm{A}=1,\ 5\mathrm{A}+\mathrm{B}=3,\ 6\mathrm{A}+3\mathrm{B}+\mathrm{C}=2,$$

from which equations we get $\mathrm{A}=1$, $\mathrm{B}=3-5\mathrm{A}=-2$, $\mathrm{C}=2-6\,\mathrm{A}-3\,\mathrm{B}=2$, so that

$$\frac{1}{v\,(v+3)}=\frac{(v+2)\,(v+3)-2\,(v+3)+2}{v\,(v+1)\,(v+2)v+3)}$$

$$=\frac{1}{v\,(v+1)}-\frac{2}{v\,(v+1)\,(v+2)}$$

$$+\frac{2}{v\,(v+1)\,(v+2)\,(v+3)}.$$

Thus it appears that the proposed series is resolvable into three others, the general terms of which all agree with the theorem. Now the sum of the infinite series whose general term is $\frac{1}{v\,(v+1)}$ appears by the theorem to be $\frac{1}{a}$, or 1, because $a=1$, and the sum of the infinite series whose general term is $\frac{-2}{v\,(v+1)\,(v+2)}$ is in like manner found to be $\frac{-2}{2}+\frac{1}{1\cdot2}=\frac{-1}{2}$; and, lastly, the infinite series whose general term is $\frac{2}{v\,(v+1)\,(v+2)\,(v+3)}$ is $\frac{2}{3}\,\frac{1}{1\cdot2\cdot3}=\frac{1}{9}$; therefore, collecting these into one, the sum of the proposed series is $1-\frac{1}{2}+\frac{1}{9}=\frac{11}{18}$, the answer.

Ex. 4. Required the sum of the infinite series

$$\frac{1}{2\cdot3\cdot4}+\frac{2}{3\cdot4\cdot5}+\frac{3}{4\cdot5\cdot6}+\frac{4}{5\cdot6\cdot7}+,\ \&c.$$

The terms of this series are evidently formed by the substitution of the numbers 2, 3, 4, successively in the function

$$\frac{v-1}{v\,(v+1)\,(v+2)}.$$

Now $v-1=v+2-3$; therefore

$$\frac{v-1}{v\,(v+1)\,(v+2)}=\frac{1}{v\,(v+1)}-\frac{3}{v\,(v+1)\,(v+2)}.$$

Thus it appears that the proposed series is reducible to two others, one having its terms produced by the substitution of 2, 3, &c. for v in the function $\frac{1}{v(v+1)}$, and the other by a like substitution in the function $\frac{-3}{v(v+1)(v+2)}$. Now, by our theorem, the sum of the first of these is $\frac{1}{2}$, and that of the second is $\frac{-3}{2}\cdot\frac{1}{2\cdot 3}=-\frac{1}{4}$, therefore the sum of the proposed series is $\frac{1}{2}-\frac{1}{4}=\frac{1}{4}$.

From these examples it is sufficiently evident how the theorem is to be applied in other cases; and it appears also, that by means of it we can sum any series whatever whose general term is of the form

$$\frac{\text{A}}{v(1+v)}+\frac{\text{B}}{v(1+v)(v+1)}+\frac{\text{C}}{v(v+1)(v+2)(v+3)}+, \&\text{c.}$$

or admits of being reduced to that form.

(16.) It deserves to be remarked, that the series

$$\frac{1}{1}+\frac{1}{2}+\frac{1}{3}+\frac{1}{4}+\frac{1}{5}+, \&\text{c.}$$

which is of a very simple form, and in appearance of the same nature as those we have summed, does not, however, admit of being treated in the same manner; and indeed if it be continued *ad infinitum*, its sum is infinite, that is, it exceeds any number which can be assigned. The truth of this assertion will be evident if we can show that a certain definite number of its terms, beginning with any proposed term, can always be found, the sum of which shall exceed an unit, or 1; for this being the case, as we can go on continually in assigning such sets of terms, we can conceive as many to be taken as there are units in any proposed number, however great; and therefore their sum, and much more the sum of all the terms of the series, from its beginning to the end of the last sets of terms, will exceed that number. Now, that this can always be done may be proved as follows:

Let the term of the series from which we are to reckon be $\frac{1}{a}$, then, if the thing be possible, and if n be the requisite number of terms, we must have

$$\frac{1}{a}+\frac{1}{a+1}+\frac{1}{a+2}+\frac{1}{a+3}\cdots+\frac{1}{a+n-1}>1.$$

Now, because

$$a\left(1+\frac{1}{a}\right)^2=a+2+\frac{1}{a},$$

$$a\left(1+\frac{1}{a}\right)^3=a+3+\frac{3}{a}+\frac{1}{a^2},$$

and in general,

$$a\left(1+\frac{1}{a}\right)^p=a+p+\frac{p\cdot p-1}{1\cdot 2}\frac{1}{a}+, \&\text{c.}$$

therefore, p being any whole number,

$$a\left(1+\frac{1}{a}\right)^p>a+p, \text{ and consequently}$$

$$\frac{1}{a+p}>\frac{1}{a\left(1+\frac{1}{a}\right)^p};$$

hence it follows, that the series

$$\frac{1}{a}+\frac{1}{a+1}+\frac{1}{a+2}\cdots+\frac{1}{a+n-1}$$

will be greater than the other series

$$\frac{1}{a}+\frac{1}{a\left(1+\frac{1}{a}\right)}+\frac{1}{a\left(1+\frac{1}{a}\right)^2}+\frac{1}{a\left(1+\frac{1}{a}\right)^3}\cdots$$

$$+\frac{1}{a\left(1+\frac{1}{a}\right)^{n-1}}.$$

Now, this last being evidently a geometrical series, of which the common ratio is $\frac{1}{1+\frac{1}{a}}$, its sum is

$$1+\frac{1}{a}-\frac{1}{\left(1+\frac{1}{a}\right)^{n-1}};$$

therefore the sum of the series

$$\frac{1}{a}+\frac{1}{a+1}+\frac{1}{a+2}+\frac{1}{a+3}\cdots+\frac{1}{a+n-1}$$

will always be greater than this expression; but if we suppose n so great that the quantity $\left(1+\frac{1}{a}\right)^{n-1}$ is equal to or exceeds a, which is evidently always possible, then the above expression for the sum of the geometrical series will be equal to 1, or will exceed 1; therefore the same number of terms of the series $\frac{1}{a}+\frac{1}{a+1}+\frac{1}{a+2}+\frac{1}{a+3}+$, &c. will always exceed 1; now this is the property of the series we proposed to demonstrate.

When $a=\left(1+\frac{1}{a}\right)^{n-1}$, then $a^2=a\left(1+\frac{1}{a}\right)^{n-1}$; but this quantity is greater than $a+n-1$, the denominator of the last term of the series

$$\frac{1}{a}+\frac{1}{a+1}+\frac{1}{a+2}+\frac{1}{a+3}\cdots+\frac{1}{a+n-1},$$

the sum of which, we have proved, will upon that hypothesis exceed unity; much more then will the sum exceed unity if we suppose the series continued until the denominator of its last term be equal to or greater than a^2. Hence, beginning with the term $\frac{1}{2}$, it appears that

$$\tfrac{1}{2}+\tfrac{1}{3}+\frac{1}{4=2^2}>1,$$

$$\tfrac{1}{5}+\tfrac{1}{6}\cdots+\frac{1}{25=5^2}>1,$$

$$\tfrac{1}{26}+\tfrac{1}{27}\cdots+\frac{1}{676=26^2}>1,$$

$$\tfrac{1}{677}+\tfrac{1}{678}\cdots+\frac{1}{458329=677^2}>1,$$

&c.

Although the sum of the series we have been considering is infinite, yet it evidently increases very slowly; indeed it is a limit to all such as have a finite sum; for every infinite series the terms of which decrease faster than the reciprocals of an arithmetical progression is always finite.

(17.) We have already explained what is meant by a *recurring series* (2.). We shall now treat briefly, first, of their origin; next, of the way in which they may be summed; and, lastly, of the manner of determining the *general term* of any particular series.

The series which is produced by the development of a rational algebraic fraction has always the property which constitutes the characteristic of the class called *recurring* (2.); and, on the other hand, any series having that property being proposed, an algebraic fraction may be found, by the expansion of which the series shall be produced.

The fraction $\frac{1+2x}{1-x-x^2}$, for example, by dividing the numerator by the denominator, is converted into the infinite series

$$1+3x+4x^2+7x^3+11x^4+18x^5+, \&\text{c.}$$

which is of such a nature that if T, T′, T″, denote any three of its succeeding terms, their relation to one another is expressed by the equation

$$T'' = T x^2 + T' x.$$

If we employ algebraic division to convert the fraction into a series, the law of its terms will not appear so readily as if we were to use the method of indeterminate co-efficients. By this method we assume the fraction equal to

$$A + B x + C x^2 + D x^3 + E x^4 +, \&c.;$$

and hence, multiplying by the denominator, and bringing all the terms to one side, as explained in ALGEBRA, § 159, we have

$$\left.\begin{matrix} A + B \\ -1 - A \\ -2 \end{matrix}\right\} x \left.\begin{matrix} + C \\ - B \\ - A \end{matrix}\right\} x^2 \left.\begin{matrix} + D \\ - C \\ - B \end{matrix}\right\} x^3 +, \&c. = 0;$$

and hence

$$\begin{array}{ll} A - 1 = 0, & C - B - A = 0, \\ B - A - 2 = 0, & D - C - B = 0, \\ & \&c. \end{array}$$

From these equations it appears that the law of the series is such as we have assigned.

The equation expressing the relation which subsists among a certain number of succeeding terms of a recurring series is called its *scale of relation.* The same name is also sometimes given to the equation expressing the connection of the co-efficients of the terms. Thus the scale of relation of the foregoing series is either

$$T'' = T x + T' x^2,$$

where T, T′, and T″ denote any three succeeding terms of the series; or it is

$$R = P + Q,$$

where P, Q, and R denote their numeral co-efficients.

(18.) We come next to show how the sum of any proposed number of terms of a recurring series may be found. Let the series continued to n terms be

$$T_{(1)} + T_{(2)} + T_{(3)} \ldots + T_{(n-2)} + T_{(n-1)} + T_{(n)},$$

where the characters $T_{(1)}$, $T_{(2)}$, &c. denote the successive terms, and the numbers (1), (2), &c. their order or place; and as, whatever number of terms is contained in the scale, the manner of summing the series is the same, we shall in what follows, for the sake of brevity, suppose that it consists of three, in which case it may be expressed thus,

$$pT_{(n-2)} + qT_{(n-1)} + rT_{(n)} = 0,$$

where p, q, r denote certain given quantities.

The scale of relation affords the following series of equations,

$$\begin{array}{l} pT_{(1)} + q\,T_{(2)} + rT_{(3)} = 0, \\ pT_{(2)} + qT_{(3)} + rT_{(4)} = 0, \\ pT_{(3)} + qT_{(4)} + rT_{(5)} = 0, \\ \ldots\ldots\ldots\ldots\ldots \\ pT_{(n-2)} + qT_{(n-1)} + rT_{(n)} = 0. \end{array}$$

Taking now the sum of these equations, we get

$$\left.\begin{array}{l} p\,\{T_{(1)} + T_{(2)} + T_{(3)} \cdots + T_{(n-2)}\} \\ +q\,\{T_{(2)} + T_{(3)} + T_{(4)} \cdots + T_{(n-1)}\} \\ +r\,\{T_{(3)} + T_{(4)} + T_{(5)} \cdots + T_{(n)}\} \end{array}\right\} = 0.$$

But, putting s for the sum of n terms of the series, this equation may manifestly be expressed thus,

$$\left.\begin{array}{l} p\,\{s - T_{(n)} - T_{(n-1)}\} \\ +\,q\,\{s - T_{(1)} - T_{(n)}\} \\ +\,r\,\{s - T_{(1)} - T_{(2)}\} \end{array}\right\} = 0.$$

Hence, after reduction, we find $s =$

$$\frac{p\{T_{(n-1)} + T_{(n)}\} + q\{T_{(1)} + T_{(n)}\} + r\{T_{(1)} + T_{(2)}\}}{p + q + r};$$

from which it appears that in this case the sum depends only on the first two and the last two terms of the series.

EXAMPLE. It is proposed to find from this formula the sum of n terms of the series

$$1 + 2x + 3x^2 + 4x^3 + 5x^4 +, \&c.$$

its scale of relation being

$$x^2\,T_{(n-2)} - 2x\,T_{(n-1)} + T_{(n)} = 0.$$

Here $p = x^2$, $q = -2x$, $r = 1$, therefore, observing that the last two terms of the series must be $(n - 1)\,x^{n-2}$ and nx^{n-1}, we have, after substituting and reducing,

$$s = \frac{1 - (n + 1)\,x^n + x^{n+1}}{1 - 2x + x^2}$$

This formula will not apply in the case of $x = 1$, because then the numerator and denominator are each $= 0$: but in such cases as this we may find the value of the function which expresses the sum by what is delivered at § 55, FLUXIONS.

(19.) The process by which we have determined the value of n terms of the series $T_{(1)} + T_{(2)} + T_{(3)} +$, &c. will also apply to the finding the rational fraction from which the series may be deduced, which is also the sum of the series continued *ad infinitum.* For in this case the equation from which we have deduced the sum being

$$\left.\begin{array}{l} p\,\{T_{(1)} + T_{(2)} + T_{(3)} +, \&c.\} \\ +q\,\{T_{(2)} + T_{(3)} + T_{(4)} +, \&c.\} \\ +r\,\{T_{(3)} + T_{(4)} + T_{(5)} +, \&c.\} \end{array}\right\} = 0,$$

that is,

$$ps + q\,\{s - T_{(1)}\} + r\,\{s - T_{(1)} - T_{(2)}\} = 0,$$

we have $$s = \frac{\{q + r\}\,T_{(1)} + r\,T_{(2)}}{p + q + r}.$$

For example, let it be required to find the fraction which, being developed, produces the series

$$1 + 2x + 3x^2 + 4x^3 +, \&c.$$

the scale of relation of which is

$$x^2\,T_{(n-2)} - 2x\,T_{(n-1)} + T_{(n)} + 0.$$

Here $p = x^2$, $q = -2x$, $r = 1$, $T_{(1)} = 1$, $T_{(2)} = 2x$; therefore, substituting in the formula, we get

$$\frac{1}{1 - 2x + x^2} = \frac{1}{(1 - x)^2}$$

for the fraction required, or for the sum of the series continued *ad infinitum.*

(20.) We come now to the last branch of the theory of recurring series which we proposed to consider, namely, how to find in any case the *general term.*

We shall begin with the most simple, and suppose the fraction to be $\frac{a}{1 - px}$, which being expounded into a series by division, is

$$a + apx + ap^2\,x^2 + ap^3\,x^3 +, \&c.$$

Here it is immediately manifest that the general term is $ap^{n-1}\,x^{n-1}$.

Next let us suppose the fraction to be $\frac{a + bx}{1 - \alpha x - \beta x^2}$. Let the two roots of the quadratic equation $1 - \alpha x - \beta x^2 = 0$ be $x = \frac{1}{p}$, $x = \frac{1}{q}$, so that $1 - px = 0$, and $1 - qx = 0$; therefore $1 - \alpha x - \beta x^2 = (1 - px)\,(1 - qx)$; thus we have

$$\frac{a + bx}{1 - \alpha x - \beta x^2} = \frac{a + bx}{(1 - px)\,(1 - qx)}.$$

Let us assume this expression equal to

$$\frac{P}{1 - px} + \frac{Q}{1 - qx},$$

where P and Q denote quantities which are to be independent of x; then, reducing to a common denominator, we have

$$\frac{a + bx}{(1 - px)\,(1 - qx)} = \frac{P + Q - (qP + pQ)\,x}{(1 - px)\,(1 - qx)}.$$

Hence, that x may remain indeterminate, we must make

$$P + Q = a,\ qP + pQ = -b,$$

and from these equations we get

$$P = \frac{ap + b}{p - q},\ Q = -\frac{aq + b}{p - q}.$$

Now, by the operation of division, we find

$$\frac{P}{1 - px} = P + Ppx + Pp^2x^2 +, \&c.$$

$$\frac{Q}{1 - qx} = Q + Qqx + Qq^2x^2 +, \&c.;$$

therefore, since $\frac{a + bx}{1 - \alpha x - \beta x^2} = \frac{P}{1 - px} + \frac{Q}{1 - qx}$, it follows that the development of the fraction $\frac{a + bx}{1 - \alpha x - \beta x^2}$, which proceeds according to the powers of x, is

$$(P + Q) + (Pp + Qq)\,x + (Pp^2 + Qq^2)\,x^2 + (Pp^3 + Qq^3)\,x^3 +, \&c.$$

And here it is evident that the general term is $(Pp^{n-1} + Qq^{n-1})\,x^{n-1}$.

Let us take as a particular example the fraction $\frac{1 - x}{1 - x - 2x^2}$, which when expanded into a series, becomes

$$1 + 0x + 2x^2 + 2x^3 + 6x^4 + 10x^5 + 22x^6 + 42x^7 + 86x^8 +, \&c.$$

Here, from the equation $1 - x - 2x^2 = 0$, we get $x = \frac{1}{2}$ and $x = -1$, so that $1 - 2x$ and $1 + x$ are divisors of the function $1 - x - 2x^2$, that is, $1 - x - 2x^2 = (1 + x)(1 - 2x)$; hence $p = -1$, $q = 2$; and since $a = 1$, $b = -1$, therefore $P = \frac{2}{3}$, $Q = \frac{1}{3}$, and the general term $(Pp^{n-1} + Qq^{n-1})\,x^{n-1}$ becomes, by substituting,

$$\left\{\frac{2}{3}(-1)^{n-1} + \frac{1}{3}\,2^{n-1}\right\} x^{n-1} = \frac{2^{n-1} \pm 2}{3}\,x^{n-1},$$

where the sign $+$ is to be taken when n is an odd number; but the sign $-$ when n is even.

Sometimes the values of p and q will come out imaginary quantities; these, however, will be found always to destroy one another when substituted in the general term.

Let us next suppose the fraction which produces a recurring series to be

$$\frac{a + bx + cx^2}{1 - \alpha x - \beta x^2 - \gamma x^3}.$$

Let $x = \frac{1}{p}$, $x = \frac{1}{q}$, $x = \frac{1}{r}$ be the three roots of the cubic equation $1 - \alpha x - \beta x^2 - \gamma x^3 = 0$, then the denominator of the fraction will be the product of the three factors

$$1 - px,\ 1 - qx,\ 1 - rx.$$

We must now assume the fraction equal to the expression

$$\frac{P}{1 - px} + \frac{Q}{1 - qx} + \frac{R}{1 - rx};$$

in which P, Q, R denote quantities which are independent of x.

The three terms of this expression are next to be reduced to a common denominator and collected into one, and the co-efficients of the powers of x in the numerator of the result are to be put equal to the like powers of x in the proposed fraction; we shall then have

$$P + Q + R = a,$$

$$(q + r)\,P + (p + r)\,Q + (p + q)\,R = -b,$$

$$qrP + prQ + pqR = c,$$

and by these equations the values of P, Q, R may be found.

Let $\frac{P}{1 - px}$, $\frac{Q}{1 - qx}$, $\frac{R}{1 - rx}$ be now resolved into series by division: then, adding the like powers of x in each, we have

$$(P + Q + R) + (Pp + Qq + Rr)\,x + (Pp^2 + Qq^2 + Rr^2)\,x^2 +, \&c.$$

for the series which is the development of the fraction

$$\frac{a + bx + cx^2}{1 - \alpha x - \beta x^2 - \gamma x^3}$$

and here the general term is evidently

$$(Pp^{n-1} + Qq^{n-1} + Rr^{n-1})\,x^{n-1};$$

and in the very same manner may the general term be found in every case in which the denominator of the fraction admits of being resolved into unequal factors.

(21.) Let us now suppose the fraction to have the form $\frac{a + bx}{(1 - px)^2}$, the denominator being the product of two equal factors; this fraction cannot be decomposed into other fractions the denominators of which are the simple factors of its denominator. We may, however, transform it into two, which shall have their numerators constant quantities by proceeding as follows: Assume the numerator $a + bx = P + Q\,(1 - px)$, then, that x may remain indeterminate, we must have $P + Q = a$, $-pQ = b$, therefore

$$Q = -\frac{b}{p},\ P = a + \frac{b}{p}.$$

The assumption of $a + bx = P + Q\,(1 - px)$ gives us therefore

$$\frac{a + bx}{(1 - px)^2} = \frac{P}{(1 - px)^2} + \frac{Q}{1 - px}.$$

Now, putting the first term of the latter side of this equation under the form $P\,(1 - px)^{-2}$, it is resolved by the binomial theorem into the series

$$P\,(1 + 2px + 3p^2x^2 + 4p^3x^3 +, \&c.);$$

the other fraction, $\frac{Q}{1 - px}$, being expanded into a series, is

$$Q + Qpx + Qp^2x^2 +, \&c.$$

Therefore the complete development of $\frac{a + bx}{(1 - px)^2}$ is

$$P + Q + (2P + Q)\,px + (3P + Q)\,p^2x^2 +, \&c.$$

and here the general term is manifestly $(nP + Q)\,p^{n-1}\,x^{n-1}$, or, substituting for P and Q their values,

$$\{npa + (n - 1)\,b\}\,p^{n-2}\,x^{n-1}.$$

(22.) In general, whatever be the form of the fraction from which a recurring series is derived, to determine the general term we must decompose the fraction into others which may be as simple as possible; and provided it be rational, and the highest power of x in the numerator at least one degree less than the highest power in the denominator, it may be always decomposed into others having one or other of these two forms

$$\frac{P}{1 - px},\ \frac{Q}{(1 - qx)^n},$$

in which expressions P, Q, p, and q, denote quantities independent of x. Each partial fraction gives a recurring series, the general term of which will be sufficiently obvious; and as the series belonging to the original fraction is the sum of these series, so also its general term will be the sum of all their general terms.

We have now treated of some of the more general methods of summing series which admit of being explained by the common principles of algebra; but the subject is of great extent, and to treat of it so as to give a tolerable notion of its various branches, would require more room than could with propriety be spared in such a work as ours.

(23.) The method of fluxions or differential calculus affords a method, almost the only general one we possess, of summing series. The general principles upon which it is applied may be stated briefly as follows. Since the integral of any differential containing one variable quantity may always be expressed by a series, on the contrary, every series may be regarded as the expression of an integral: when any series then is proposed, we must endeavour to find the differential expression of which that series is the integral; and as we can always find the integral of a differential, at least by approximation, within given limits, we may thence determine, if not the exact, at least the approximate value of any infinite series. We shall now show how this principle may be applied in some particular cases.

Problem I. It is proposed to find the sum of n terms of the series

$$x + 2x^2 + 3x^3 + 4x^4 \cdots + nx^n.$$

Let the sum be denoted by s. Then, multiplying all the terms by $\frac{dx}{x}$, we have

$$\frac{sdx}{x} = dx + 2xdx + 3x^2dx \cdots + nx^ndx.$$

Let the integral of both sides be now taken, and the result is

$$\int \frac{sdx}{x} = x + x^2 + x^3 + x^4 \cdots + x^n.$$

Now the series on the right-hand side of this equation is a geometrical progression, the sum of which is known to be $\frac{x - x^{n+1}}{1-x}$ (Algebra, § 56). Therefore

$$\int \frac{sdx}{x} = \frac{x - x^{n+1}}{1-x},$$

and, taking the differentials,

$$\frac{dx}{x} = \frac{dx - (n+1)x^ndx + nx^{n+1}dx}{(1-x)^2},$$

Hence we find

$$s = \frac{x - (n+1)x^{n+1} + nx^{n+2}}{(1-x)^2}.$$

This result agrees with that formerly found (17) of this article.

Problem II. It is proposed to sum the infinite series

$$1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \frac{1}{11} +, \&c.$$

We may consider this series as a particular case of the more general series

$$x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} +, \&c.$$

namely, that in which $x = 1$. Putting therefore the sum $= s$, and taking the differentials, we have

$$ds = dx\,(1 - x^2 + x^4 - x^6 +, \&c.).$$

Now the series in the parenthesis is obviously the development of the rational fraction $\frac{1}{1+x^2}$, therefore $ds = \frac{dx}{1+x^2}$, and taking the integral $s = \text{arc}\,(\tan. = x) + c$, radius being unity. (Fluxions, § 139.) Now, when $x = 0$, all the terms of the series vanish, so that in this case $s = 0$; and as when $x = 0$, arc $(\tan. = x) = 0$; therefore c, the constant quantity added to complete the fluent, is 0, and we have simply $s = \text{arc}\,(\tan. = x)$, and when $x = 1$, then $s = \frac{1}{2}$ a quadrant $= {\cdot}7853982$.

Problem III. Required the sum of the infinite series

$$\frac{x}{1 \cdot 2} + \frac{x^2}{2 \cdot 3} + \frac{x^3}{3 \cdot 4} + \frac{x^4}{4 \cdot 5} +, \&c.$$

Putting s for the sum, and taking the differentials, we get

$$ds = \frac{dx}{x^2}\left(\frac{x^2}{2} + \frac{x^3}{3} + \frac{x^4}{4} + \frac{x^5}{5} +, \&c.\right)$$

Now the series in the parenthesis is evidently equal to $-x -$ Nap. log. $(1-x)$, (see Algebra, sect. xix.); therefore

$$ds = -\frac{dx}{x} - \frac{dx}{x^2} \times \text{Nap. log. } (1-x).$$

To find the integral, let us put v for the function $\frac{1}{x}$ log. $(1-x)$, then, taking its fluxion, we have

$$dv = -\frac{dx}{x^2} \times \log.\,(1-x) - \frac{dx}{x(1-x)},$$

and $-\frac{dx}{x^2} \times \log.\,(1-x) = dv + \frac{dx}{x(1-x)}$;

therefore, substituting, we get

$$ds = dv + \frac{dx}{x(1-x)} - \frac{dx}{x}$$

$$= dv + \frac{dx}{1-x};$$

and taking the integrals,

$$s = v - \log.\,(1-x) + c$$

$$= \frac{\log.\,(1-x)}{x} - \log.\,(1-x) + c.$$

To determine the constant quantity c, let us take $x = 0$; then in this case all the terms of the series vanish, so that $s = 0$, also $\log.\,(1-x) = \log.\,1 = 0$; and since in general $\frac{\log.\,(1-x)}{x} = \frac{1}{x}\left(-x - \frac{x^2}{2} - \frac{x^3}{3} -, \&c.\right) = -1 - \frac{x}{2} - \frac{x^2}{3} -$, &c. when $x = 0$, then $\frac{\log.\,(1-x)}{x} = -1$; therefore $0 = -1 + c$, and $c = 1$; hence it appears that

$$s = \frac{\log.\,(1-x)}{x} - \log.\,(1-x) + 1$$

$$= \frac{(1-x)\log.\,(1-x)}{x} + 1.$$

Example. Let $x = \frac{1}{2}$, then our formula gives $\frac{1}{1 \cdot 2 \cdot 2} + \frac{1}{2 \cdot 3 \cdot 2^2} + \frac{1}{3 \cdot 4 \cdot 2^3} + \frac{1}{4 \cdot 5 \cdot 2^4} +, \&c. = 1 -$ Nap. log. $2 = {\cdot}3068528$.

Problem IV. Let the series to be summed be

$$1 + \frac{m}{n}x + \frac{m+1}{n+1}x^2 + \frac{m+2}{n+2}x^3 +, \&c.$$

Putting s for this series, let all its terms be multiplied by x^{n-1}, so that the exponent of x in each may be identical with its denominator; the result is

$$sx^{n-1} = x^{n-1} + \frac{m}{n}x^n + \frac{m+1}{n+1}x^{n+1} + \frac{m+2}{n+2}x^{n+2} +, \&c.$$

and hence, taking the differentials

$$x^{n-1}ds + (n-1)sx^{n-2}dx = (n-1)x^{n-2}dx + mx^{n-1}dx + (m+1)x^ndx + (m+2)x^{n+1}dx +, \&c.$$

Let both sides of this equation be now multiplied by x^{m-n}, and it becomes

$$x^{m-1}dx + (n-1)sx^{m-2}dx = (n-1)x^{m-2}dx + mx^{m-1}dx + (m+1)x^mdx + (m+2)x^{m+1}dx +, \&c.$$

Putting now the single character dp for the fluxional expression which forms the first member of this equation, we get, by taking the fluents of both sides,

$$p = \frac{n-1}{m-1}x^{m-1} + x^m + x^{m+1} + x^{m+2} +, \&c.$$

$$= \frac{n-1}{m-1}x^{m-1} + x^m(1 + x + x^2 + x^3 +, \&c.);$$

but the series in the parenthesis is the development of $\frac{1}{1-x}$, therefore

$$p = \frac{n-1}{m-1}x^{m-1} + \frac{x^m}{1-x}.$$

Taking now the fluxions, and substituting instead of dp the expression it was put to represent, we get

$$x^{m-1}ds + (n-1)\,sx^{m-2}dx$$
$$= (n-1)\,x^{m-2}dx + \frac{mx^{m-1}dx}{1-x} + \frac{x^m dx}{(1-x)^2};$$

and this, after reduction, becomes

$$ds + \frac{n-1}{x}\,sdx = \frac{(n-1)dx}{x} + \frac{mdx}{1-x} + \frac{xdx}{(1-x)^2}.$$

This fluxional equation being of the first degree and first order, its primitive equation may be found (from the general formula given in Fluxions, § 171) to be

$$s = \frac{1}{x^{n-1}} \times \int \left\{ (n-1)\,x^{n-2}dx + \frac{mx^{n-1}dx}{1-x} + \frac{x^n dx}{(1-x)^2} \right\};$$

and this again, by remarking that $\int (n-1)x^{n-2}dx = x^{n-1}$, and that

$$\int \frac{mx^{n-1}dx}{1-x} = \frac{mx^n}{n(1-x)} - \int \frac{mx^n dx}{n(1-x)^2},$$

may be reduced to

$$s = 1 + \frac{mx}{n(1-x)} + \frac{n-m}{nx^{n-1}} \int \frac{x^n dx}{(1-x)^2},$$

The remaining fluent $\int \frac{x^n dx}{(1-x)^2}$ may be found by § 101, Fluxions, and it must be so taken, that after being multiplied by $\frac{n-m}{nx^{n-1}}$, it shall vanish when $x = 0$; for then this hypothesis will make the whole function which expresses the value of s vanish, except its first term 1, as it ought to do.

Example. Let us suppose $n = 2$, then

$$\int \frac{x^2 dx}{(1-x)^2} = x + \frac{x}{1-x} + 2\log.(1-x),$$

and

$$\frac{2-m}{2x} \int \frac{x^2 dx}{(1-x)^2} = \frac{(2-m)\,x}{2(1-x)}$$
$$+ \frac{2-m}{x}\log.(1-x),$$

the fluent being here taken as directed. In this case, after collecting the terms, we get s, or

$$1 + \frac{m}{2}x + \frac{m+1}{3}x^2 + \frac{m+2}{4}x^3 +, \&c.$$
$$= \frac{1}{1-x} + \frac{(2-m)}{x}\log.(1-x).$$

(24.) There is a branch of the doctrine of series which is of considerable importance in pure mathematics, as well as in many physical inquiries, and in the science of astronomy; it is called the *Interpolation* of series.

To interpolate a series is to interpose among its terms others which shall be subject to the same law, or which shall be formed in the same manner as the original terms of the series; or, in other words, it is to find the value of one or more terms by means of others which are given, and which may be either at equal or unequal intervals from one another, the places of the given terms as well as of those sought being supposed known.

It is easy to see that this problem may be applied to the construction of logarithmic tables; for we may regard the logarithms of the natural numbers 1, 2, 3, 4, &c. *ad infinitum,* as the terms of a particular series of which the numbers themselves are the indices; thus having given the logarithms of some numbers, we may by interpolating deduce from them the logarithms of others.

Again, in astronomy we may consider the numbers which express the successive observed positions of a celestial body as the terms of a series, their indices being the intervals of time between the observations and some assumed epoch, and the problem we are considering will enable us to determine the position at any instant different from the times of actual observation, provided the intervals between the observations be small, and the instant for which the position is sought not very remote from those at which the observations were made.

(25.) To illustrate the nature of the problem to be resolved, let us consider some particular case, as, for example, the arithmetical series

$$a,\ a+d,\ a+2d,\ a+3d,\ a+4d,\ \&c.$$

Let t and t' be two given terms of the series which are at any distance from one another, and let n and n' be their indices, or numbers which denote their places in the series. Also let y be any term whatever, and x its index. Then, by the nature of an arithmetical series,

$$t = a + (n-1)d,\ t' = a + (n'-1)d,$$
$$y = a + (x-1)d.$$

Now, as there are here three equations, each involving the quantities a and d, we may eliminate both these quantities by the common rules (Algebra, sect. vii.); and this being done, we get

$$(x-n')(t'-t) = (n'-n)(y-t');$$

and hence we find this expression,

$$y = \frac{x-n'}{n-n'}t + \frac{x-n}{n'-n}t',$$

which is a general formula for interpolating any arithmetical series; and it is observable, that it is entirely independent both of the first term and common difference.

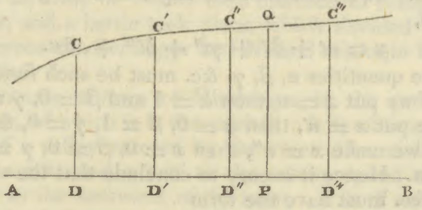
Example. The 7th term of an arithmetical series is 15, and the 12th term is 25: it is required to find the 10th term.

Here $n = 7,\ n' = 12,\ x = 10;$
$t = 15, t' = 25,\ y$ is sought.

Therefore, by the formula,

$$y = \frac{2}{5} \times 15 + \frac{3}{5} \times 25 = 21, \text{ the answer.}$$

(26.) The mode of investigation by which we have found a formula for the interpolation of an arithmetical series will apply also to others, if the law according to which the terms are formed be known; in general, however, the law of a series to be interpolated is either not known, or it is not taken into account, and we only consider the absolute magnitudes of certain terms, and the numbers expressing their places in the series. To resolve the problem generally with these *data*, it is usual to proceed as follows: Let a straight line AB, and a point A in it, be assumed as given in position, and let there be taken the segments AD, AD′, AD″, AD‴, &c., proportional to the numbers denoting the places of the terms of a series reckoned from any term assumed as a fixed origin; and at the points D, D′, D″, let there be erected perpendiculars proportional to the terms themselves. Let us now suppose a curve to pass through C, C′, C″, C‴, &c.; then, if it be so chosen that its curvature may vary gradually in its progress from point to point, without any abrupt changes of inflection, and, moreover, if the terms (which we may suppose to be either at equal or unequal distances) are pretty near to one another, it is easy to conceive, that if AP be taken equal to the number expressing



the place of a term between C″D″, C‴D‴, any two others, the term itself will, if not exactly, at least be nearly, expressed by PQ, the ordinate to the curve.

As an infinite variety of curves may be found that shall pass through the same given points, in this respect the problem is unlimited; it is, however, convenient to assume such as are simple and tractable. The parabolic class possess these properties, and accordingly they are commonly employed.

Let us then express the ordinates CD, C′D′, C″D″, C‴D‴, &c. which are the given terms of the series, by

$$t,\ t',\ t'',\ t''',\ \&c.$$

and the abscissæ AD, AD′, AD″, AD‴, or the numbers denoting the order of the terms, by

$$n,\ n',\ n'',\ n''',\ \&c.$$

Put y for PQ, a term to be interpolated, and x for AP its place. Then, considering x and y as indefinite co-ordinates, a parabolic curve that shall pass through the points C, C′, C″, C‴, &c., will have for its equation

$$y = \mathrm{A} + \mathrm{B}x + \mathrm{C}x^2 + \mathrm{D}x^3 +, \&c.$$

the number of terms on the right-hand side being supposed equal to that of the given points, and A, B, C, &c. being put to denote constant quantities. To determine these, we must consider that when $x = n$, then $y = t$, and that when $x = n'$, then $y = t'$, and so on; therefore, substituting the successive corresponding values of x and y, we get

$$\begin{aligned}
t &= \mathrm{A} + \mathrm{B}n + \mathrm{C}n^2 + \mathrm{D}n^3 +, \&c. \\
t' &= \mathrm{A} + \mathrm{B}n' + \mathrm{C}n'^2 + \mathrm{D}n'^3 +, \&c. \\
t'' &= \mathrm{A} + \mathrm{B}n'' + \mathrm{C}n''^2 + \mathrm{D}n''^3 +, \&c. \\
t''' &= \mathrm{A} + \mathrm{B}n''' + \mathrm{C}n'''^2 + \mathrm{D}n'''^3 +, \&c. \\
&\&c. \qquad\qquad \&c.
\end{aligned}$$

This series of equations must be continued until their number be the same as that of the co-efficients A, B, C, D, &c. If we now consider t, t', t'', &c. and n, n', n'', &c. as known, and A, B, C, &c. as unknown quantities, we may determine these last by eliminating them one after another from the above equations, as is taught in ALGEBRA. And the values of A, B, C, &c. being thus determined and substituted in the general equation, we shall have a general expression for y in terms of x, the number denoting its place and known quantities; and this is in substance the solution originally given of the problem by Sir Isaac Newton, who proposed it in the third book of his *Principia*, with a view to its application in astronomy.

A celebrated foreign mathematician (Lagrange) has, in the *Cahiers de l'Ecole Normale*, given a different form to the expression for y. He has observed that since, when x becomes n, n', n'', n''', &c. successively, then y becomes t, t', t'', t''', &c. It follows that the expression for y must have this form,

$$y = \alpha t + \beta t' + \gamma t'' + \delta t''' +, \&c.$$

where the quantities α, β, γ, &c. must be such functions of x, that if we put $x = n$, then $\alpha = 1$ and $\beta = 0$, $\gamma = 0$, &c. and if we put $x = n'$, then $\alpha = 0$, $\beta = 1$, $\gamma = 0$, &c.; and again, if we make $x = n''$, then $x = 0$, $\beta = 0$, $\gamma = 1$, &c. and so on. Hence it is easy to conclude that the values of α, β, γ, &c. must have the form

$$\alpha = \frac{(x-n')\,(x-n'')\,(x-n''')}{(n-n')\,(n-n'')\,(n-n''')}, \&c.$$

$$\beta = \frac{(x-n)\,(x-n'')\,(x-n''')}{(n'-n)\,(n'-n'')\,(n'-n''')}, \&c.$$

$$\gamma = \frac{(x-n)\,(x-n')\,(x-n''')}{(n''-n)\,(n''-n')\,n''-n''')}, \&c.$$

$$\delta = \frac{(x-n)\,(x-n')\,(x-n''')}{(n'''-n)\,(n'''-n')\,(n'''-n'')}, \&c.$$

$$\&c.$$

and here the number of factors in the numerator and denominator must be each equal to the number of given points in the curve. This formula would be found to be identical with that which may be obtained by the method indicated in last article, if we were to take the actual product of the factors and arrange the whole expression according to powers of x. It possesses however one advantage over the other, viz. that of admitting of the application of logarithms.

We shall now show the application of this formula.

Ex. 1. Having given the logarithms of 101, 102, 104, and 105, it is required to find the logarithm of 103.

In this case we may reckon the terms of the series forward from the first given term, viz. log. 101, so that we have

$$\begin{aligned}
t &= \text{log. } 101 = 2{\cdot}0043214, & n &= 0, \\
t' &= \text{log. } 102 = 2{\cdot}0086002, & n' &= 1, \\
y &= \text{log. } 103 = \text{term sought}, & x &= 2, \\
t'' &= \text{log. } 104 = 2{\cdot}0170333, & n'' &= 3, \\
t''' &= \text{log. } 105 = 2{\cdot}0211893, & n''' &= 4.
\end{aligned}$$

Substituting now in the general formula, we get

$$\alpha = \frac{1\times-1\times-2}{-1\times-3\times-4} = -\frac{1}{6},\quad \gamma = \frac{2\times1\times-2}{3\times2\times-1} = \frac{2}{3},$$

$$\beta = \frac{2\times-1\times-2}{1\times-2\times-3} = \frac{2}{3},\quad \delta = \frac{2\times1\times-1}{4\times3\times1} = -\frac{1}{6},$$

$$\begin{aligned}
\text{Therefore } y &= -\frac{t}{6} + \frac{2t'}{3} + \frac{2t''}{3} - \frac{t'''}{6} \\
&= \tfrac{2}{3}(t'+t'') - \tfrac{1}{6}(t+t''') \\
&= 2{\cdot}0128372, \text{ the answer.}
\end{aligned}$$

Ex. 2. Given a comet's distance from the sun on the following days in December, at twelve at night, to find its distance December 20.

December 12. distance 301, Dec. 24. distance 715,
21. 620, 26. 772.

Here we shall estimate the places of the terms from the time of the first position, viz. December 12. Therefore

$$\begin{aligned}
t &= 301, & n &= 0, \\
y &\text{ is sought}, & x &= 8, \\
t' &= 620, & n' &= 9, \\
t'' &= 715, & n'' &= 12, \\
t''' &= 772, & n''' &= 14.
\end{aligned}$$

In this case the general formula gives us

$$\alpha = \frac{1}{63},\ \beta = \frac{6}{45},\ \gamma = -\frac{2}{3},\ \delta = \frac{8}{35},$$

therefore

$$\begin{aligned}
y &= \frac{t}{63} + \frac{64t'}{45} - \frac{2t''}{3} + \frac{8t'''}{35}. \\
&= 586{\cdot}3, \text{ the answer.}
\end{aligned}$$

We shall conclude this article with a brief enumeration of the best works on the subject which we have been treating of.

Bernoulli, *Ars Conjectandi*; Newton, *Methodus Differentialis*; Taylor, *Methodus Incrementorum*; Stirling, *Methodus Differentialis, sive Tractatus de Summatione et Interpolatione Serierum*; Euler, *Institutiones Calculi Differentialis*; Emerson's Method of Increments; Emerson's Differential Method; De Moivre, *Miscellanea Analytica*; Lagrange, *Théorie des Fonctions Analytiques*; *Traité des Différences et des Séries*, a sequel to Lacroix's work on the *Calcul Différentiel*; Dr Hutton's Mathematical and Philosophical Tracts; Spence's Essay on the Theory of the various orders of Logarithmic Transcendents, with an Inquiry into their Applications to the Integral Calculus, and the Summation of Series.

nagur.

SERINAGUR, a principality or province of Northern Hindustan, situated chiefly between the 30th and 31st degrees of north latitude, and between the 77th and 79th of east longitude. It is divided from Thibet by the great mountain-wall of the Himalaya that bounds Hindustan on the north; it has the great plain of the Ganges on the south; on the east the rivers Dauli, Alcananda, and Ramgunga form its limits; and on the west it is bounded by the stream of the Jumna. It is estimated to be a hundred and forty miles in length by sixty in breadth, and to contain an area of nine thousand square miles. It contains two geographical divisions, namely, Gurwal proper, which occupies the whole of the lower ranges of hills and the sources of the Ganges, comprehending the hilly and mountainous region from which that river springs. In former times this principality also included Kumaon. In 1814 the Ghoorkhas possessed the whole country extending northward to the dependencies of China. Since their expulsion a new division has been effected, by which it has been separated into two distinct portions; the British government having retained the Deyrah Doon, the passes of the Ganges, and the Jumna, at either extremity of that valley, as also all the country to the eastward of the Alcananda and Bhagirathi, which last-mentioned tract has been annexed to Kumaon, and the remainder restored to the expatriated rajah. The territories to the eastward are therefore at present bounded by the Alcananda, from Radraprayag until its conjunction with the Bhagirathi, and thence to the plains by the united streams of the Ganges, and above Radraprayag, where the Alcananda receives the Mandakeri by the latter river. All the territories to the east of that line have been permanently annexed to Kumaon.

The whole face of this country towards Lalldong southward forms one vast assemblage of steep and lofty hills, of the rudest forms, and jumbled together in all directions. They are sometimes disposed, with an appearance of regularity, in parallel chains of no great extent, and shut in at their termination by narrow ridges running across the valleys at right angles. The summits are sharp and narrow, rising abruptly; and the distance between each range being very short, the valleys are in consequence so confined that it would be difficult in many of them to find room for an encampment of a thousand men. The aspect of these mountainous regions is very different. There are many of the ridges stony and naked, affording no shelter for birds or wild animals, while others are covered with trees, and always green, being covered with a luxuriant carpeting of shrubs and fragrant flowers. The eastern parts of the country to the Ganges consist of lower ranges of hills, extending eastward to an undefined extent, and covered with extensive forests of oak, holly, horse-chestnut, fir, and beds of strawberries, equalling in flavour those in Europe. Over this extensive and mostly desert country inhabitants are very thinly scattered, a great proportion of it being left in the undisturbed possession of the wild animals, such as the elephant, which is, however, greatly inferior in size and quality to the Chittagong elephant, on which account it is seldom domesticated; the tiger, the leopard, and generally all the other animals which are found to range among the tropical forests. The country is chiefly watered by the Ganges, and its head streams the Bhagirathi and Alcananda, by the junction of which it is formed at Devaprayaga. The latter is a considerable river, and is joined by its tributaries the Mandakini, the Pinden, the Mandaioki, the Birke, and the Dauli; while the Bhagirathi is joined by the Bilhang. Some of these rivers bring a large accession of water to the main stream; and they have most of them their remote sources in the Himalaya Mountains. None of these streams being fordable, and, besides, descending with all the violence of mountain-torrents, and their channel being too much encumbered with rocks and stones to admit the use of boats, they are crossed by rope and platform bridges at the most convenient points of communication; while the roads are merely footpaths running along the slope of a mountain in the direction of the principal streams and water-courses, and being only practicable in many places for hill-porters. (See the article HINDUSTAN.) Sheep and goats are also trained to traverse the difficult road, and to act as beasts of burden. They are loaded with small bags, containing twelve pounds of grain each, and are despatched in flocks of from 150 to 200, under the charge of two or three shepherds with their dogs. A steady old well-trained ram is extremely serviceable in carrying goods in these mountainous countries, particularly grain, which forms a principal article of commerce. From the higher region salt is brought back.

Serinagur.

In 1796, while Serinagur or Gurwal included Kumaon, and was an independent principality, the revenues amounted to five lacs of rupees per annum, which sum was made up of the duties on imports and exports, the land-rents, the working of mines and washing of gold. The other sources of revenue arose from a tax on the importation of rock-salt and borax from Bootan; of musk in pods, chowries, hawks, and male and female slaves from the countries bordering on Bhadrinath; of cotton cloths of all descriptions from the province of Oude; and of salt from Lahore.

Gold is found among the sands of most of the mountain-streams. The principal places where it is gathered are Carnaprayaga, Pacenkoonda, Devaprayaga, Rickercase, and Lakherighaut. There are in the mountains mines of copper, which in 1816 were let out for one year at 1850 rupees. Prior to the Ghoorkha invasion these mines were said to yield 52,000 rupees. During the confusion consequent on that event some of them have been choked up with rubbish; and to recover them from their present condition would require more capital than any native ever possesses. At Nagpoor and Dhunpoor, to the north and north-east of Serinagur, are two copper-mines, which are said to produce fifty per cent. At Dessouly, a considerable distance to the east, there is a lead-mine; and iron is produced in many parts of the country. Near Jarachi Ghaut, in the eastern quarter of the province, there is a quarry of very fine marble.

The ancient name of this province was Gurwal; and while it was an independent state the rajah's forces were estimated at 5000 men, armed with matchlocks, bows and arrows, and swords and shields, but without discipline. In 1791 the Nepaulese made an attempt to reduce this country, but met with such unexpected resistance, that they desisted from the attempt. From this date, however, the Serinagur rajah became tributary to the Ghoorkhali dynasty. In 1803 an army of 10,000 men marched to complete the conquest, and a battle took place, which decided the contest between the Serinagur and Nepaul rajahs in favour of the latter.

SERINAGUR, a town of Hindustan, in the province of Serinagur, of which it is the capital. It is situated in the centre of a valley watered by the river Alcananda, which extends a mile and a half to the eastward, and the same distance to the westward, of the town. It is of an elliptical form, being in length about three quarters of a mile, and much less in breadth. The houses are built of rough stone and mud, generally raised to a second floor, and covered with slate. They are remarkably crowded together; and the streets are so narrow as scarcely to leave room for two persons to pass. The house of the former rajahs is in the middle of the town, and is the largest, being raised to a fourth story, and built of a coarse granite. The town is now in a ruinous condition, having been reduced to poverty and insignificance by a variety of causes; by the invasion of the Nepaulese at the end of the year 1803, the earthquake which took place in the same year, the encroachments annually made by the Alcananda, and, finally, by the oppressive government under its Ghoorkhali rulers. The inhabitants are chiefly Hindus, the number of Mahommedan families not exceeding sixty or seventy, and most of these being petty shopkeepers. The Hindu inhabitants are chiefly the descendants of emigrants from the Doab and province of Oude. Serinagur is the seat of an inconsiderable trade, the most profitable branch of which consists of a traffic in silver and specie, which is carried on to a considerable amount by the leading persons in the town, who are agents of the great banking-houses at Najibabad and in the Doab, and who are employed in the sale of merchandise and coins. The other articles of trade are the produce of the hills, consisting of coarse hempen cloth, hemp, lead, copper, drugs, gums, wool, and a sort of flannel made of wool. From Bootan are imported cow-tails, musk, saffron, borax, salt, drugs of different kinds, and a few shawls that are sent circuitously from Cashmere. Hawks are also brought from the hills. The articles received in exchange are coarse cotton and woollen cloths, silk, spices, Lahore salt, sugar, and tobacco. The air of Serinagur is unfavourable to strangers, on which account many of the merchants forsake it during the rainy season. Long. 79. 18. E. Lat. 30. 11. N.

SERINGAPATAM, a celebrated city of Hindustan, in the province of Mysore, of which it is the capital. Its situation is remarkable, being at the upper end of an island four miles in length by one and a half in breadth, formed by the Cavery, which is here a large and rapid river, having a broad channel, that is, however, impeded by rocks and fragments of granite. The proper name of this city is Siri Runga Patan, or the city of Sri Ranga, corrupted in common language into Patana. It has been known as a fortress from a very early period; the fort is situated at the west end of the island; its area is about a mile, and it is an immense mass of building, unfinished, and its defences injudiciously constructed. The fortifications exhibit the long straight walls and square bastions of the Hindus; and the glacis is in many parts so high that it sheltered the assailants. The suburbs occupy the middle and highest part of the island, and are about half a mile square. The streets are, like those of most eastern towns, narrow and confused; nor are there any public buildings which are noted for elegance or splendour in the eyes of Europeans. They have all a mean appearance. Hyder's palace, named the Lolbang, which was finished in 1780, when he was occupied in the wars of the Carnatic, and to which he never returned, is situated at the east end of the island. It is two stories in height, and, according to Lord Valentia, by whom it was visited, it is by no means an inelegant building, though mud is the material of which it is constructed. The ground-floor was very public, and seems to have been occupied by the attendants. Above are excellent apartments, and balconies opening into courts in which the sultan usually sat and gave audience. It was prettily painted, but, owing to the want of windows, was too gloomy for a European habitation, and has accordingly been altered and improved by the British residents. It is situated in a garden, which was beautiful, but was destroyed during the siege of the city. Adjoining to this building is the tomb of Hyder, where now rests all that was royal of this Mussulman dynasty, namely, Hyder, his wife, and Tippoo, under tombs of black marble elevated about eighteen inches from the ground, and covered with rich cloths, which have a canopy over them. The whole building, with its dome, its brilliantly polished black marble columns, and its mosque annexed, has a handsome effect. In the verandah are buried several of the family; and on the outside, upon an elevated platform which goes round the whole building, are the tombs of several faithful servants. The British government allow 2000 pagodas annually to the Moulahs for reading the Koran, and for musicians to perform the nobut. The palace in the city is a very large building, surrounded by a massy and lofty wall of stone and mud, and of a mean appearance. All the buildings are now converted to very different uses from those for which they were originally intended. Hyder's palace is the residence of a surgeon; his seraglio is converted into a European hospital; and Tippoo's seraglio has become a barrack for artillery. His private abode is occupied by the resident, and his public apartments by European troops. There is a palace built by Tippoo near the town, which was the residence of General Wellesley. The upper floor consists of one central room, with four others at the corners, and verandahs below them, all very curiously painted; a verandah below covers each side, on the walls of which is painted the famous battle with Colonel Baillie. Other paintings adorn the walls, in which Hyder and Tippoo are represented as conquerors, and subject princes are painted below.

In 1610, Seringapatam was taken from the fallen dynasty of Bijanagur by the rajah of Wadeyar, and made the capital of Mysore. The town was increased and the fortifications improved by his successors. But it was Hyder and his son Tippoo who took pleasure in strengthening and embellishing this the capital of their dominions. It was then that it arrived at that degree of splendour and strength which attracted the cupidity and afterwards foiled the attempts of the neighbouring powers. It was afterwards besieged by the Mahrattas and by the nizam's troops, and was rescued from their attacks by Hyder consenting to pay large sums of money for its security. In 1800, according to a register of the houses, the fort or city contained 4136 houses and 5900 families, and the suburbs 2216 houses and 3335 families. Estimating five persons to each house, the city and suburbs will be found to contain 31,895 persons, independently of a strong garrison and its numerous followers. During the reign of Tippoo, the island of Seringapatam was estimated to contain 150,000 inhabitants. They were greatly diminished during the siege, and after the storming of the place; but many have since been attracted to the rajah's residence at the city of Mysore, and many Mahommedans who originally came from the Carnatic have returned, after the destruction of Hyder's dynasty. The manufactures of Seringapatam and its vicinity were never considerable, and principally consisted of military stores and camp equipage. Timber sells here at a high price, being brought principally by land-carriage from the Western Ghauts. Bread is also dear, which compels the Europeans to subsist upon rice. Good vegetables and excellent meat are, however, to be had in abundance. In February 1792, Seringapatam was invested by a formidable British force, amounting to 400,000, including followers of every description. Tippoo had not the means of withstanding this numerous host; and his intrenched camp being stormed with great loss, he was compelled to yield to the humiliating terms imposed upon him by his conquerors, to relinquish half his dominions, and to pay to them the sum of three and a half millions. In 1799, war being again declared by the British against Tippoo, an immense force, under General Harris, advanced against the capital, which was invested by the British and the nizam's forces on the 14th of April, and was stormed, with a great slaughter of the garrison, in the afternoon of the 4th of May. Tippoo himself was killed under a gateway, by a party, it is supposed, of the twelfth regiment of foot, but by whom is not known, no individual having ever appeared to claim the honour; nor was it discovered who obtained possession of his valuable necklace of pearls. The British have ever since retained possession of the island, which now forms one of the collectorships under the Madras presidency. The travelling distance from Madras is 200 miles, from Hyderabad 406, from Poonah 525, from Bombay 622, from Nagpoor 727, from Calcutta 1170, and from Delhi 1321 miles. Long. 76. 51. E. Lat. 12. 26. N.

SERINGHAM, an island formed by the Cavery, opposite to Trichinopoly, in the Carnatic. The river separates into two branches, and about thirteen miles eastward these branches again approach; but the northern, which is at this place twenty feet lower than the southern branch, is permitted to run waste into the sea, and is termed the Coleroon; whilst the southern, which retains the name of Cavery, is led into a variety of channels to irrigate the province of Tanjore. Near the east end of the island is formed an immense mound, to prevent the waters of the Cavery from descending into the Coleroon. This island is celebrated for two Hindu temples, the largest of which is situated about a mile from the western extremity of the island, and is surrounded by seven square enclosures built of brick, the walls of which are twenty-five feet in height and four feet in thickness. These enclosures are at the distance of 350 feet from each other, and have each four gates opposite the cardinal points. The outward wall is nearly four miles in circumference, and its gateway to the south is ornamented with pillars, several of which are single stones thirty-three feet in length and five in diameter. The British pay so much deference to the Hindu superstitions, that no European has yet entered this temple. It is resorted to from all parts of India by pilgrims seeking absolution for their sins. A tax is levied on them; and this fund, besides supporting a number of dancing girls, who are prostitutes to the Brahmins, yields a revenue to the British government. In 1751, during the siege of Trichinopoly, the French and their allies took possession of the island of Seringham. In 1752, the French force was compelled to surrender to Major Laurence. The Hindu sanctuaries in these temples were respected by the troops of both nations, neither of whom sought access into the temples.

SERINO, a city of Italy, in the Neapolitan province of Ulteriore. It stands between two hills, and contains ten parish churches, with 7500 inhabitants, who are employed in making woollen goods and in spinning silk. There is also a very large annual fair held at Serino; and near to it are the ruins of the ancient Roman city Sabatia.

SERLE'S ISLAND, in the Southern Pacific Ocean. It is seven or eight miles long, and four or five broad, with a lagoon in the middle. Long. 223. E. Lat. 18. 18. S.

SERMATTA, an island in the Eastern Seas, about twenty-two miles in length and six in breadth. Long. 129. 13. E. Lat. 8. 9. S.

SERONGE, a town of Hindustan, in the Mahratta territories, and province of Malwah. It is situated in a fine open country, well cultivated, and has the remains of ancient prosperity and greater population than at present. The bazaars are strong, and built of stone; and a large caravanserai still remains. The adjacent country is an open plain. It was formerly the scene of the Pindarie plunderers; and the villages are in consequence mostly in ruins. It is 165 miles north-east from Oojain, 389 from Benares, 595 from Bombay, 849 from Calcutta. Long. 78. E. Lat. 24. 8. N.

SERPENS, in *Astronomy*, a constellation in the northern hemisphere, called more particularly *Serpens Ophiuchi*. The stars in the constellation Serpens are, in Ptolemy's catalogue, eighteen; in Tycho's, thirteen; in Hevelius's, twenty-two; and in the British catalogue, sixty-four.

SERPENTS, OR OPHIDIAN REPTILES.

IN our article REPTILIA (see *Encyclopædia Britannica*, vol. xix. p. 150) we deemed it advisable to postpone the consideration of the Ophidian order, in the hope that our readers might be benefited by the termination of MM. Dumeril and Bibron's work, the most complete and careful publication by which the history of the reptile race has been as yet illustrated.[1] But having been disappointed in that expectation, we proceed to fill up our sketch of the class in question from other equally authentic sources. The student will bear in mind that our present treatise, relating to the third great order of reptiles, called OPHIDIA (from ὄφις, *a serpent*), interpolates at the page above referred to, and connects, in the natural system, the SAURIA, or lizard-like reptiles, with the BATRACHIA or frogs, sirens, and salamanders. We also take leave to remind our readers (and this the more emphatically, seeing that the imperfect treatise now put forth is the last of the zoological essays for this work likely to proceed from the present pen), that the study of nature is a high and solemn calling, for the proper performance of which, according to the measure of each capacity, men are as accountable to their Creator as they are for the discharge of all other duties, whether moral, intellectual, or professional. We may not say to him who desires an entrance into that magnificent temple which God has erected in his works, "Take off thy shoes, for the place on which thou standest is holy ground;" but we shall say, "Divest yourself of arrogance, conceit, and self-delusion; worship closely, continuously, and fervently; and ever bear in mind that you are yourself a reptile, debarred by the very constitution of your nature from seeing any thing otherwise than in a glass darkly." Should not this feeling act as a monitor in favour of humility and distrust? From whence come contentions among you? From ignorance and folly, from the blinding effect produced by the undue importance which every man is apt to attach to his own small doings, and the frequent absence of that kindly consideration with which each Christian observer should view the labours both of predecessor and contemporary. It is indeed woful to think that those to whom God has given a taste for pursuits in themselves so pleasing and consolatory should so often disgrace their lofty calling by meanness and malice, and that irritability and "all uncharitableness" should in any way arise among men who, when not willingly blinded, may perceive at least a glimpse of what the divine Milton (with how much of inward light, though himself so "dim-suffused!") has beautifully called "the bright countenance of truth shining amid the still air of delightful studies." If naturalists are the priests of nature, then let them bear in mind that theirs is no vain or selfish ministration, and so conduct themselves

> As ever in their great task-master's eye.

The exact lines of demarcation which separate the primary orders of the reptile race are somewhat difficult to draw, as in truth must always be the case wherever there are strong affinities of form and habits. *Natura non facit saltum*, is a saying the truth of which the student of her manifold wonders must ever remember; and in our present department especially, there are several very singular creatures, which so combine the characters of two contiguous orders, that well-instructed naturalists differ as to whether they should terminate the one or commence the other. Thus Baron Cuvier's last *Ophidian* genus is *Cæcilia*, which Professor Bell regards as a Batrachian reptile, or rather as belonging to his separate class Amphibia, which, after the example of Blainville and Latreille, he constitutes by means of the entire Batrachian order.[1] Thus also *Lacerta apoda* of Pallas, though furnished on each side with a small bone analogous to the femur, and pertaining to an actual pelvis concealed beneath the skin, is yet classed by the great French anatomist with the Ophidians, being, so to say, the "very head and front of their offending;"[2] while several systematic writers range our *Anguis fragilis*, and other snakes commonly so called, among the lizards. An American reptile, *Anguis ventralis* of Linn., now forms Daudin's genus *Ophisaurus*, the name of which (derived from ὄφις, *serpent*, and σαῦρος, *lizard*) implies the peculiar combination now referred to. The Saurian genus *Seps*, described at the conclusion of our former treatise, is characterized by Cuvier as having an elongated body, "tout-à-fait semblable à celui d'un orvet" (*Anguis*); and, on the other hand, the same author enters upon his Ophidian order by means of the *Anguidæ*, or slow-worms, which he simply describes as "des seps sans pieds." These, and other examples which it would be easy to adduce, demonstrate the close connection which subsists between the Saurian and Ophidian orders.

---

[1] *Erpétologie Générale, ou Histoire Naturelle complète des Reptiles*, four vols. 8vo, with plates (containing hitherto only the Chelonian and a large portion of the Saurian orders). Paris, 1834–38.

It has indeed been customary to class among serpents whatever reptiles combined the absence of limbs with an extremely lengthened form of body; but a more rigorous observation will demonstrate that several species which, in accordance with that principle, will take their place as serpents, are yet in their prevailing organic structure removed from them in most essential points, the chief resemblance being that of the external and extremely lengthened form. Now this attenuated aspect, and absence of all the ordinary locomotive members, are likewise exhibited by several Saurian reptiles, and of course in an increased degree as they actually approach the serpent or Ophidian tribes; but the two characters just mentioned do not convert them from one order to another, being still held, as it were, in subordination to the general structure.[3]

We bring forward these observations at present, chiefly that the reader may understand why we commence our treatise on serpents by a brief sketch of several species which in truth we can scarcely regard as serpents at all, however raised "to that bad eminence" by many noted writers. We might have placed them at the termination of the Saurian order of our former article Reptilia; but the fact being that we did not do so, we feel it incumbent on us, before proceeding to the serpents properly so called, to present a short notice of their names and nature. In doing this we shall follow for a space the arrangement of Baron Cuvier, presuming that the reader will now understand our views regarding the doubtful nature of all those genera which precede the true serpents, of the advent of which due notice will be given.

The French anatomist defines serpents as,—reptiles without feet, which advance by means of sinuous movements of the body. He divides them into three great groups,—the Anguidæ or slow-worms,—the true serpents (subdivided into, 1st, double movers, *i. e.* the genera *Amphisbæna* and *Typhlops;* 2dly, serpents properly so called, containing all the actually Ophidian species),—and the naked serpents, composed of the single genus *Cæcilia*.

We commence, then, with the

ANGUIDÆ, OR SLOW-WORMS.

These still exhibit the bony head, the teeth, the tongue of *Seps*, and the eye is furnished with three eyelids. They correspond to the ancient unrestricted genus Anguis of Linnæus, and are characterized externally by imbricated scales covering the whole body. The species now form four minor genera, of which the first three still exhibit beneath the skin certain small bones corresponding to those of the shoulder and pelvis.

Genus Pseudopus, Merrem. Tympanum visible externally. A prominence on each side of the anus, containing a small bone analogous to the femur, and appertaining to a true pelvis hid beneath the skin. Rudiments of the anterior extremities barely manifested by an inconspicuous fold, containing no interior humerus. One of the lungs is a quarter less than the other. The scales are thick and imbricated, and between those of the back and belly are some smaller scales, which produce a longitudinal furrow on either side.

Of the species, the earliest known is *P. Pallasii*, Cuv., *Lacerta apoda*, Pallas,—discovered in the south of Russia by the naturalist last named.[4] It measures from one to two feet in length, and the colours are ferruginous above, pale yellow beneath. The scales of the back are smooth, those of the tail carinated. This species occurs also in Hungary and Dalmatia, and the specimen figured by Dr Shaw[5] was procured in Greece by Dr John Sibthorpe, the professor of botany in the university of Oxford. M. Durville discovered another species (which bears his name) in the Archipelago.[6] See Plate CCCCXLIII. fig. 1.

Genus Ophisaurus, Daudin. No external appearance even of the hinder extremities, but the tympanum is still apparent, and the scales exhibit a plication or folding upon each side of the trunk. The smaller lung only equals a third of the greater.[7]

The best known species is *Oph. ventralis*,—*Anguis ventralis*, Linn.,—an American reptile, common in the southern states of the union. It is of a greenish yellow, spotted above with black. Its tail is longer than its body, and the creature itself is so brittle and easily broken, even in the living state, as to be known by the name of glass serpent. According to Catesby, "a small blow of a stick causes the body to separate, not only at the place struck, but at two or three other places, the muscles being articulated quite through the vertebræ."[8]

---

[1] *Encyclopædia of Anatomy and Physiology*, part i. p. 91. These amphibian orders are as follows: 1st, *Amphipneurta*, containing the Sirens and Proteans; 2d, *Anoura*, the frogs and toads; 3d, *Urodela*, the salamanders; 4th, *Abranchia*, the genera Menopoma and Amphiuma; and, 5th, *Apoda*, the genus Cæcilia. "It is easy," adds Mr Swainson, "to perceive that this last passes into the first by means of the dipod Sirens, and thus the whole form a circular group more or less perfect in its connecting links." (*Cabinet Cyclopædia*, vol. cxvi. p. 86.)

[2] See *Règne Animal*, ii. 69.

[3] "Un examen comparatif," observes M. Schlegel, "des objets m'a démontré que ces Sauriens anomaux, c'est-à-dire, à formes alongées et à extrémités rudimentaires, appartiennent toujours par l'ensemble de leur organisation à quelque espèce de l'une ou l'autre des familles de cet ordre, parmi lesquelles ils doivent être distribués. On ne peut nier, par exemple, qu'il y a un passage graduel des Scinques à l'Anguis et aux Acontias, par l'intermède des Scinques brachypus, decreensis, serpens, seps, du Pygodactyle et du Bipes,—êtres moins différens entre eux par leur organisation que par leurs formes, et qui ne composent qu'une seule famille, celle des Scincoïdes, de laquelle on ne saurait exclure ni les Ablephares ni les Gymnophthalmes. Le même passage graduel existe dans la famille des Lézards, des genres Lacerta et Tachydromus au Monodactyle; on y peut ajouter comme espèce anomale le Pygopus. On pourrait rapprocher dans la méthode le Tetradactyle, le Chalcis, le Pseudopus, et l'Ophisaurus. Viennent enfin la famille des Amphisbènes,—Chirotes, Leposternon, Amphisbæna, et celle des Typhlops,—Typhlops, Rhinophis, Uropeltis." (*Physiognomie des Serpens*, i. p. 2.)

[7] Of the cranium of this genus, Cuvier has remarked, "C'est une vraie tête de Saurien." *Règne Animal*, iii. 430.

[8] *Carolina*, ii. plate 59.

Amphisbænidæ.

Genus Anguis, Cuv. No extremities visible externally. Tympanum concealed beneath the skin. Maxillary teeth compressed and hooked,—no teeth upon the palate. Body surrounded by imbricated scales, without plication on the sides. One of the lungs is a half less than the other.

The English slow-worm, *Anguis fragilis*, is common over a great part of Europe.[1] It is very smooth, of a shining brownish-gray above, inclining to reddish on the sides, and bluish-black upon the under surface. It rarely measures more than a foot in length. It lives on insects and small mollusca, excavates circuitous holes in the earth, of several feet in extent, and with more than one issue. It is an innocent and gentle creature, remarkable for stiffening itself so much when seized as sometimes to break in two. Hence its specific name of *fragilis*.

Genus Acontias, Cuv. No osseous pieces corresponding to the sternum and pelvis, the shoulder-blades and clavicles. Anterior ribs united to each other inferiorly by cartilaginous prolongations. Teeth small and conical: "Je crois," says Cuvier, "leur en avoir aperçu quelques-unes au palais."[2] Muzzle enclosed in a kind of mask. One lung of medium size, and another of very small dimensions.

To this genus belongs the speckled slow-worm of Shaw, *Anguis Meleagris*, Linn., a native of the Cape of Good Hope.[3] Its tail is much shorter and more obtuse than that of the British slow-worm. Its upper surface is spotted longitudinally with brown. Africa produces other species, one of which, according to Cuvier (*Ac. cæcus*), is entirely blind.

We now reach Baron Cuvier's second great division, the **True Serpents**, consisting of all those genera which exhibit no vestige of either shoulder or sternum, but have a great portion of the circumference of the body surrounded by the ribs. The vertebræ articulate by means of a convex facette at one end, entering into a concave facette of that which follows. (See Plate CCCCXLIV. fig. 2*a* and 2*b*.) The third eye-lid and the tympanum are wanting, but the osselet of the ear exists beneath the skin, and its handle passes behind the tympanic bone. Several still manifest a remnant of the posterior members hid beneath the skin, or even showing themselves externally under the form of small hooks.[4] The first two genera are scarcely entitled to the designation of *True Serpents;* and Baron Cuvier has himself drawn a line between them and those which he names *Serpents properly so called*, although the two terms seem not particularly distinctive. The reptiles in question form the tribe *Double Marcheurs* of Cuvier, and may be named

AMPHISBÆNIDÆ, OR BLIND-WORMS.

The lower jaw still continues, as among the preceding groups, supported by a tympanic bone, articulated directly to the cranium, the two branches of that jaw being soldered together anteriorly, while those of the upper one are fixed to the cranium and the intermaxillary bone. This formation both produces an equality of dimension between the head and the rest of the body, and also prevents that peculiar power of dilatation for which the genuine serpents are so remarkable. (See Plate CCCCXLIII. fig. 1*a*.) Their general form, according to Cuvier, "leur permet de marcher également bien dans les deux sens," a fact, however, which that great observer does not seem to state as from the "ocular proof," and for the confirmation of which we have sought in vain in the work of any well-instructed traveller. The bony frame-work of the orbit is incomplete behind, the eye is extremely small, and the body is covered with scales. The windpipe is elongated, the heart placed far backwards, and the anus situate close to the extremity of the body. None of the known species is venomous. Of the two genera, the one is closely related to *Chalcis* and *Chirotis*, the other to *Anguis* and *Acontias*.

Genus Amphisbæna, Linn. The entire body covered by circular ranges of quadrangular scales. A range of pores anterior to the anus. Teeth of a conical form, numerous on the jaws, none upon the palate; only a single lung.

The species are South American reptiles, to which an ancient classical name has been, with no great propriety, applied. (See Plate CCCCXLIII. fig. 2.) The white one, *Amph. alba*, Linn., measures from a foot and a half to two feet in length, and is proportionably of a bulky form.[5] It inhabits Brazil, where its native name of *Ibriaram* signifies Lord of the Earth. It was first described by Maregrave, who, however, states erroneously that it is venomous, and will wound either with head or tail. It preys on insects, and is often found near ant-hills. Another species, from Martinique (*Amph. cæca*, Cuv.), is stone-blind.

It may be observed in passing, that the genus *Lepostemon* of Spix is composed of Amphisbænæ, of which the anterior part of the body is furnished below with several plates, which interrupt the ranging of the circular rings. They have no pores anterior to the anus, the head is short, and the muzzle slightly projecting. Example, *Lep. microcephalus*, Spix,—*Amph. punctata* of Prince Maximilian (Neuwied).

Genus Typhlops, Schneider. Body covered with small imbricated scales (as in *Anguis*, with which group the species were for a long time combined). Muzzle advanced, furnished with plates. Tongue long and forked; eye in the form of a minute point, scarcely visible through the skin; anus almost terminal; one lung four times larger than the other.

These, as Cuvier remarks, are small serpent-like creatures, which bear a great resemblance to earth-worms. They inhabit the warmer countries both of America and the old world. Some have the head obtuse, and of equal diameter with the body. Such is *T. braminus*, Cuv., the punctulated slow-worm of Shaw, and *rondos talooloopam* of Dr Russel.[6] It is a diminutive reptile, measuring about six inches in length, with the thickness of a hen's quill. It is of a cream-colour, powdered over with innumerable black dots. It is common in Vizagapatam, and, according to the author last named, is vulgarly reputed mischievous. It is described as moving with great swiftness; and a specimen immersed in spirits remained alive for more than ten minutes. Others (and these the majority) have the muzzle depressed and obtuse, and furnished anteriorly with several plates. Example, *T. reticulatus*.[7] A few have the front of the muzzle covered by a single broad plate. Such is *T. subargenteus* (*Anguis lumbricalis*, Linn. and Lacép.), the silvery snake of Brown.[8] Finally, there are one or more peculiar species, in which the muzzle terminates in a small conical point, and the posterior extremity is enveloped by a horny buckler of an oval form. We here place *T. Philippinus*, Cuv., which measures about eight inches in length, and is entirely of a black colour. We presume that Dr Shaw's snouted slow-worm, *Anguis nasuta* (*A. rostrata* of Weigel[9]), though differing in colour, is nearly allied, and ought to be placed in the same genus.

We now arrive, "by lingering steps and slow," at the genuine serpents, or

OPHIDIAN REPTILES, PROPERLY SO CALLED.

The principal characteristic of the serpent race consists in an extremely elongated body, clothed with scales, destitute of limbs, and furnished with a tail, or caudal extremity. Locomotion is effected by lateral undulations, aided by the scales externally, and by the ribs within. Although the general form, viewed in relation to its transverse dimensions, is concentred to an extremely small diameter, the different parts are capable of great enlargement, which admits in many cases of their swallowing bodies bigger than themselves. In conformity with this peculiar structure, even the bony portions of the head are not so knit together as in other animals, but, with the exception of the parts which protect the brain, are capable of a certain degree of separation. (See Plate CCCCXLIII. fig. 1*b*.) The development of the tympanic bones; their mode of attachment; the mobility which they enjoy from not being fixed to the cranium by their lower extremity; finally, the structure of the under jaw, the two branches of which are capable of separation in consequence of being united by elastic ligaments instead of symphysis; all combine to produce the vast swallowing powers of these reptiles. The entire absence of limbs is accompanied by an equal absence of those solid portions, such as the sternum and pelvis, which unite the limbs with the body. The ribs are free for the same reason, and thus readily admit both of the occasional enlargement of the intestinal cavity, and of that extreme pliancy of form for which all the species are remarkable, whether they creep, climb, or swim. To facilitate these various movements, the general envelope is minutely subdivided into numerous compartments, the scales of the lower surface being usually much larger than those of the upper, and subserving the place of feet, the ribs being attached to the lateral margin of the inner surface of these abdominal plates. The space of bare skin between the scales is greater among serpents than other reptiles, and on the throat this bare expanse forms a longitudinal cleft, known by the name of gular furrow.

The true Ophidians are closely connected to the Saurian order by the preceding genera *Amphisbæna* and *Typhlops*, which certainly form a passage from one of those great ordinal groups to the other. It is these connecting links that render precise definitions, drawn from a few apparent characters, so difficult, if not impossible. "Il est très facile," observes M. Schlegel, "de se faire une idée d'un serpent, lorsqu'on prend pour type une des espèces où tous les caractères de l'ordre se trouvent réunis ; mais il est difficile de consigner des marques distinctives qui separent d'une manière tranchée les Ophidiens des Sauriens."[1] Thus the gular furrow which characterizes all serpents except the genus *Acrochordus*, exists also among lizards, and several other Saurian reptiles. A few Ophidians even exhibit vestiges of the hinder extremities, analogous to what we may observe among the so-called apodal Saurians, although there is reason to suspect that the parts alluded to represent, in the latter the pelvis, in the former the actual extremities.[2] Perhaps the characters deduced from the bones of the cranium would afford the best distinctions between the two orders, were it not that in these, too, certain species of the genera *Typhlops* and *Uropeltis* make a near approach to the true Ophidians. It may be well, however, to state briefly the distinguishing features in the cranial osteology of the latter order. The bones of the face in serpents never form a fixed mass perforated by the nostrils, and incased by sutures in each other; and the intermaxillary bone, trigonal, and compressed in its form, is always free, and to a certain extent moveable, that is, never soldered by sutures to the maxillaries on either side. The maxillaries themselves, when united to the anterior frontals, are so merely by a narrow attachment, always preserving a certain mobility; and the lateral margins of the nasal bones are free throughout their whole extent. No Ophidian reptile has thick conical teeth perpendicularly incased; they rather resemble hooks curved backwards, with sharp points; and we believe that all serpents, with the exception of the genus *Oligodon*, have the palate armed with teeth resembling those on the maxillæ, whilst in the Saurian order the palatine teeth exist only in the form of small irregular asperities.

From the preceding brief sketch it may be inferred, that the most peculiar character of serpents consists in their mode of locomotion, and their extraordinary powers of deglutition. These conditions modify their entire organization, for the former determines the general shape of the body, and the latter that of the internal parts. On examining the position of the intestines, we find that these organs, which in the majority of other vertebrated beings occupy several spacious cavities, are in the Ophidians enclosed within a long and narrow cylinder. It is obvious that this disposition cannot prevail without great changes in the form of the viscera; and the disturbance alluded to is even destructive of bilateral symmetry. We thus find the heart sometimes far removed from, at others closely approached towards, the head, according as the stomach is more or less extended; it is thus also that most frequently there is only a single lung, sometimes extending in front of the heart, but usually placed behind that organ, and almost always terminated by a species of sack of greater or less extent, and serving as a reservoir of air. The liver, for the same reason, assumes a narrow ribbon shape, extending from the heart to the pylorus. The gall-vessel, that it may not be interrupted in its functions by the repletion of the stomach, is removed from the liver, and placed in the same curve of the duodenum as that which receives the pancreas and the spleen. The stomach resembles a lengthened narrow cylinder. Then follow the intestines, of which the numerous inflections are filled with fat, and which, after descending in a straight line, terminate in the cloaca. The lower portion of the abdominal cavity not being sufficiently spacious for the reception of the rest of the organs, there thence results an anomalous disposition of the kidneys, testicles, and ovaries. "La verge enfin, et un organe sécréteur, sont logés dans la queue." These peculiar forms, however, of the majority of the internal parts of serpents exercise no influence over their functions; for, on more minute investigation, we find that they vary not only in distinct species, but in different individuals of the same species.

The disposition of the external organs, on the contrary, present much more constant forms; but these parts are modified by the habits of the species, whether arboreal, terrestrial, or aquatic. The mode of locomotion is, however, very uniform, the movement being nearly the same which aids a serpent while gliding on the surface of the ground, traversing the depths of lakes and rivers, or climbing around the umbrageous branches of forest-trees. The lateral undulations of the body suffice for these progressions; and it is chiefly the sea-snakes that make use of their tails, which are expressly organized for that special purpose, acting as a scull. The degree of rapidity depends in a great measure on the nature of the surface in which the motion is

---

[1] *Essai sur la Physiognomie des Serpens*, par H. Schlegel. La Haye, two vols. 8vo, 1837. Of this, the most recent and complete work on our present department with which we are acquainted, we have availed ourselves largely in the following treatise.

[2] We have exhibited these parts as they exist in the genus Boa. See Plate CCCCXLIV. figs. 1, 1*a*, and 1*b*.

Ophidian Reptiles.

exercised. Serpents drag themselves along with difficulty over glass or any polished body, but make their way with great alacrity over any earthy irregular surface, or through tangled vegetation. For the exercise of these movements it is of course necessary that the bones and muscles should be fitly disposed; and every one who has examined a properly prepared serpent, must have been struck at once by the multiplicity and uniformity of its parts. The ribs and vertebræ are almost all alike in their formation, and it is only towards the caudal extremity that the bones diminish in bulk.

As all the vertebræ of serpents carry ribs, the usual distinctions of cervical, dorsal, and lumbar, do not exist; and it follows, that the number of ribs always corresponds to that of vertebræ. Moreover, as the scaly articulations of the skin always correspond to the ribs, which are their levers, so the number of abdominal plates agrees with the amount of ribs and vertebræ. This number varies not only with the species, but the individuals, and to so surprising an extent, that we not unfrequently find a difference in the same species, amounting to thirty or even fifty vertebræ. The number of vertebræ of the body, properly so called, rarely exceeds 300, and is never fewer than 100; the vertebræ of the tail, on the contrary, are sometimes reduced to five, although in other cases they amount to from 150 to 200. The ribs are more numerous in serpents than in any other class of created beings, several having above 500,—that is 250, or upwards, on each side of the spinal column. We here figure the skeleton of the common ringed snake of England,—*Tropidonotus natrix*. See Plate CCCCXLIV. fig. 2.

The muscles exhibit various modifications in the different species. In some they are remarkable for their considerable size, and for the extraordinary development of tendons, especially among the venomous kinds. This organization is necessary for the production of that force and energy with which their undulating movements are often executed. The muscles which produce these effects are situate along the sides of the back, and on the anterior face of the vertebræ; but as the ribs likewise exercise the function of locomotive organs, the numerous muscles which are attached to these parts greatly facilitate the lateral movements. The muscles of serpents being greatly interlaced, it becomes difficult to describe them singly, and their comparison with analogous parts in the higher orders is by no means easy. These anatomical details, however, are not to be expected in the present publication. We therefore refer the reader to the works of Home,[1] Hübner,[2] Dugès,[3] Duvernoy,[4] Meckel,[5] and Schlegel.[6]

The muscles of serpents, as of other reptiles, preserve their irritability for a long time after what we may regard as the actual death of the animal; for these creatures, although deprived of their head, and divested of their skin, will continue to exhibit muscular movements for several weeks, if kept in a moist condition. Swammerdam, in his *Biblia Naturæ*, has proved, both by his figures and descriptions of frogs, that even at that early period (1666), that peculiar galvanic effect was demonstrated in the muscles of these reptiles, which at a future period gave rise to such important discoveries regarding the phenomena of Voltaic electricity.

A few words may be said regarding the supposed vestiges of the hinder extremities observable in certain serpents. Several species exhibit on each side of the anus a small hook or crotchet, half concealed by scales. The existence of these parts has been long recognised, but we believe it is to Professor Mayer of Bonn that we owe a more precise knowledge of their nature. The only Ophidian genera in which they have been hitherto precisely observed, are *Tortrix*, *Python*, and *Boa*. They are most developed among the Boas, and the huge size of these reptiles admits of a more satisfactory examination. (See Plate CCCCXLIV. figs. 1, 1*a*, and 1*b*.) These vestiges, then, consist of an assemblage on each side, of three principal osseous pieces, and of two small accessory portions attached at the point of articulation of the tibia and tarsus. The terminal bone, which alone appears externally, is in the form of a crotchet, covered by a hard and scaly skin. When a longitudinal incision is made in the flesh, we find that the interior piece, which is the most developed, more or less S shaped, and comparable to the tibia, is prolonged with its free extremity into the abdominal cavity. The middle portion, on the contrary, which seems to represent the tarsus, is thick, short, slightly arched, and completely concealed within the flesh. This apparatus is moved by flexor and extensor muscles of a sufficiently simple structure. The use of these vestiges of the posterior members is still unknown. Their feeble development debars the idea of their contributing in any way to locomotion. Certain observers maintain that they are prehensile organs, which give firmness of position on whatever bodies are embraced by the circumvolutions of the tail and trunk; or that they may even subserve the generative process. They exist in both sexes.

When in a state of entire repose, the majority of serpents love to roll themselves into a spiral mass, with the head in the centre, slightly raised above the other portions. Possessing the power of bending their bodies in almost all directions, we at the same time frequently find them simply extended on the ground or herbage in a sinuous curve. To produce progressive motion, they merely unrol the body, and bending it into successive lateral sinuosities, bring into play the numerous points of contact presented by the anterior extremities of the ribs, and thus push along with great facility. These reptiles are frequently observed to raise the anterior portion of their body into an erect position, supporting themselves on the tail and part of the abdomen, as if with a view to survey the scene around them. The body, itself, is then usually quite stiff and straight, although some assume a more curved attitude, besides exhibiting a peculiar swelling or enlargement of the neck. When suspended perpendicularly from the branch of a tree, the great Boas exhibit scarcely any sign of life or motion. They descend simply by dropping themselves downwards, their peculiar form and great elasticity of structure preventing their receiving any injury from the fall; and when they reach the ground, this rapid movement, so far from proving hurtful, aids by its impulsion their terrestrial progress.

Frequent mention has been made by vague observers, of serpents which could execute a retrograde movement,—gliding backwards as easily as in an ordinary direction. This fact has not been established on the authority of any instructed naturalist, and may well be doubted, notwithstanding what the ancients have said of the Amphisbæna (αμφὶς and βαίνειν, *marching both ways*), a reptile alleged to have a head at either end, and supposed to be endowed with the faculty of progressing in both directions.[7] The name, originally applied to a species of the ancient world, probably the *Eryx*, has been erroneously bestowed by modern naturalists (following the example of the Portuguese) on a tribe of serpents peculiar to America,—a country which knew not Aristotle.

The majority of serpents (both of the innocent and the colubriform venomous kinds) defend themselves against the

Ophidian Reptiles.

attack of their enemies by darting upon them, with the head elevated, so as to enable them to bite with greater energy. A few, such as the Najas, raise a considerable portion of the anterior of the body, so as to assume a very singular position. Most of them give utterance to a sharp hissing sound as a prelude to battle; and they also produce a peculiar blowing, by forcing the air rapidly through the nostrils. Several species throw themselves upon their prey with a great and sudden bound, usually seizing it by the throat; while others encircle it by a tortuous embrace, thus pressing it to death by sinewy folds. The venomous kinds make use of the same means to obtain their food as they do to defend themselves from threatened danger. Quietly stretched along the earth, they will attack indifferently whatever incommodes them; but knowing the potency of their empoisoned fangs, they are satisfied by the infliction of a murderous bite, without recourse to muscular pressure.

As snakes swallow their food entire, and without mastication, their teeth serve merely to wound and retain their prey, or to instil into it the envenomed fluid. This deadly matter is the product of certain glands of the head. These are of two kinds; the one composed, like the salivary glands of quadrupeds and birds, of numerous small granules, which secrete a fluid analogous to saliva, and destined to prepare the food for digestion; the other, of a very different nature, forming a thick sack, of which the interior is divided into numerous compartments, and distilling a liquid which, by its fatal effects on the principle of life, becomes a dreadful instrument of destruction. The salivary glands are common alike to all Ophidian reptiles, but scarcely a fourth of the entire species are provided with those which secrete the poison. The teeth which conduct this fatal fluid into the wound are hollow and pierced at each extremity. They are always situate towards the anterior end of the maxillary bone, are covered by the gums, which there form a kind of sheath, and are always kept bent when in repose. The rest of the teeth, and the whole of those of the innocuous kinds, are solid, with the exception of the hollow which contains the nutritive organ of the tooth. Although these large anterior fangs are characteristic of the poisonous kinds, we yet find a considerable number of innocuous species, of various genera, which have the jaws armed with one or two teeth larger than the others, and usually furrowed by a cleft extending along the anterior face. These grooved teeth are always situate at the base or posterior extremity of the maxillaries, and it is but seldom that we perceive a second on the middle portion of the jaw. Their sole function is believed to be the pouring into their wounded prey an abundant supply of saliva secreted by the posterior part of the salivary glands, which are most voluminous in the region occupied by the teeth in question. The organization of these posterior glands entirely resembles that of the ordinary salivary ones; and recent observation has demonstrated, that the bite of species belonging to the genera ***Dryophis***, ***Dipsas***, and others with furrowed teeth, is followed by no fatal results, at least to the human race.[1]

In studying in detail the teeth of the Ophidian reptiles, we may perceive a gradation from the solid to the hooked teeth. Each tooth in fact consists, in its earliest development, of a kind of lamella with curved margins, so as to open as it were on its anterior face. In the so-called solid teeth, this opening has become filled by the union of the margins at an early period; it continues open for a longer time in the hooks of the most venomous kinds, but in the completed state they exhibit only the two orifices destined for the entrance and emission of the poison,—the lower one continuing to preserve the character of a longitudinal cleft. In other poisonous species we find analogous fangs, but with a continuing vestige of the groove which formerly united the two orifices. Finally, the furrow in the lengthened posterior teeth of certain innocuous species, is nothing more than the permanence of the groove now mentioned.

The solid teeth occur indifferently in all Ophidian reptiles; but their number, form, and position, vary in the different species. With the exception of the genus *Oligodon*, which is unprovided with palatine teeth, there are always four rows of teeth in the upper jaw (see Plate CCCCXLIII. fig. 1*c*), and two in the lower. Intermaxillary teeth are not observable, except in the genus ***Python***, and occasionally in ***Tortrix scytale***,—the number rarely exceeding four (see figure last referred to). These solid teeth are usually all of equal length; but in the Boas they enlarge towards the extremity of the muzzle (fig. 11), while the reverse is the case in several species of ***Coluber***, ***Tropidonotus***, &c. The ***Lycodons*** exhibit some teeth more largely developed than the others at the anterior extremity of the maxillaries; those of ***Dryophis*** and ***Psammophis*** are rather unequal, several being even greatly elongated towards the centre of the jaw; those of certain species of ***Dipsas***, ***Homalopsis***, &c. are often furrowed; while other genera, such as ***Xenodon***, ***Coronella***, and several kinds of ***Homalopsis***, have the base of the maxillaries armed with a strongly developed tooth of a solid structure. The number of teeth, in general, obviously varies in relation to the development of the maxillaries, and of the dental bone of the lower jaw.

The poison-gland, which forms so peculiar a character of the noxious kinds, is enclosed in a thickish tendinous envelope, hard and tenacious to the touch, and diminishing backwards into the form of a narrow ribbon, by which it is attached to the articulation of the lower jaw. Anteriorly this envelope is also restricted to a canal-shaped space, which stretches along the maxillaries, and then descends towards the orifice already mentioned, of the anterior face of the base of the hooked fang. (See Plate CCCCXLIII. fig. 10). Among the poisonous serpents properly so called, this canal is folded when the fangs are in a state of repose, but easily extends in conformity with the movement of the maxillary bones. The interior of the poison-gland is subdivided into a great number of minute cells, produced by very slender partitions, which cross each other at an angle more or less acute. To this peculiar structure, so dissimilar to that of the salivary glands, is due the secretion called poison, from its fatal effect when mingled with the blood of any living creature. It is true, that the bite of even the most innocent animal may sometimes produce the most disastrous results, by a concourse of peculiar circumstances, such as the temperature of the climate, the psychological or pathological condition of the creature bitten, or the rabid fury of that which has aggressed, and for this reason the bite of innocuous serpents may have sometimes proved fatal even to the human race; but the poison of the injurious kinds holds its noxious qualities in its very nature, although the circumstances just alluded to may render more deadly its destroying powers.

The poison of snakes, when fresh, may be described as a transparent limpid fluid, of a greenish-yellow colour, slightly gluey, viscous, adhering to other objects when dried, and evaporating without burning when exposed to fire. It sinks in water, and when mingled with it by shaking, produces a troubled and somewhat whitish appearance. It partakes greatly of the nature of mucus; and when placed in contact with any re-active substance, we discover that it is neither acid nor alkaline; there is nothing peculiar in its odour, and when applied upon the tongue it produces a sensation resembling that of fresh fat. Our recorded notices on the subject are, however, somewhat contradictory. Dr Mead and his associates, in certain experiments on the poison of the viper, inform us that that fluid, "when diluted with a little warm water, was very sharp and fiery when tasted with the tip of the tongue, as if the tongue had been struck through with something scalding or burning; this sensation went off in two or three hours; and one gentleman who would not be satisfied without trying a large drop undiluted, found his tongue swelled, with a little inflammation, and the soreness lasted two days." The Abbe Fontana, on the contrary, describes it as of no particular acrimony of taste, but rather resembling oil or gum; and Dr Russel makes the same statement regarding the poison even of the Cobra de Capello, a species much more venomous than any viper. The accounts of its effect upon the stomach, when taken internally, also show that doctors differ. It is long since Celsus said, "nam venenum serpentis non gustu sed in vulnere nocet." Boerhaave quotes the well-known case of Jacob Sozzi, who, at the court of the Duke of Tuscany, is alleged to have taken three drams of this poison, without experiencing any bad consequences; while Fontana affirms, that although its internal effect is not like that of a bite or puncture, it cannot be swallowed with impunity. On this point the older authors, as Dr Shaw informs us, also disagree. Matthiolus asserts, that even when sucked from a wound it has proved fatal; while others confirm the prevailing opinion of ancient writers, and the experience of Cato's soldiery, that it is harmless when so received. The practice, indeed, of the Psylli and Marmarides of old,

---

[1] The glands in the head of serpents have been discussed in numerous publications. See, among others, Ranby, *Phil. Trans.* No. 401, p. 377; Tiedemann, *Mém. de l'Acad. de Munich*, 1813, p. 25; Cloquet, *Mém. du Mus.*, vii. p. 62; Demoulins ap. Magendie, *Journ. de Physiol.* iv. p. 274; Meckel, *Archiv*, i. 1; and Duvernoy, *Ann. des Sciences Nat.* xxvi. and xxx. Various observations bearing on the subject will also be found in the well-known writings of Redi, Mead, Fontana, and other physiologists.

> Tame, at whose voice, spell-bound, the dread Cerastes lay,

probably proceeded upon this principle of suction. These Psylli were African tribes, and were employed, according to Lucan, by Cato, for the recovery of such of his men as had been bitten by serpents during their march among the Libyan deserts. The heroic Roman is also said to have assured his followers, who feared to drink, even in "a dry and desert land," of the translucent fountains, lest they too should be infected by serpents, that, however noxious might be the bite of these envenomed reptiles, yet the poison must lose its effects when mingled with so pure an element.

> And now with fiercer heat the desert glows,
> And mid-day gleamings aggravate their woes;
> When, lo! a spring amid the sandy plain
> Shews its clear mouth to cheer the fainting train.
> But round the guarded brink in thick array
> Dire Aspics roll'd their congregated way,
> And thirsting, in the midst, the dreadful Dipsas lay.
> Blank horror seized their veins, and at the view
> Back from the fount the troops recoiling flew.
> When, wise above the crowd, by cares unquell'd,
> Their awful leader thus their fears dispell'd:
> Let not vain terrors now your minds enslave,
> Nor dream the serpent brood can taint the wave;
> Urged by the fatal fang their poison kills,
> But mixes harmless with those bubbling rills.
> Dauntless he spoke, and bending as he stood,
> Drank with cool courage the suspected flood.

The poison of the viper, according to Boerhaave, is rendered inactive by digestion in the stomach and bowels, so that it will not afterwards exert its fatal influence on the blood; "for a whole ounce of this venom taken by the mouth will not kill an animal, while at the same time a small needle only dipped in the same fluid, and taking up perhaps not more than the hundredth part of a drop, when thrust into the blood of a living creature, almost infallibly destroys."[1] The following is Bruce the traveller's well-known but extraordinary narrative. "I will not hesitate to aver that I have seen at Cairo (and this may be seen daily, without trouble or expense) a man who came from above the catacombs, where the pits of the mummy-birds are kept, who has taken a cerastes with his naked hand from a number of others lying at the bottom of the tub, has put it upon his bare head, covered it with the common red cap he wears, then taken it out, put it in his breast, and tied it about his neck like a necklace; after which it has been applied to a hen, and bit it, which has died in a few minutes; and, to complete the experiment, the man has taken it by the neck, and beginning at the tail, has ate it as one would do a carrot or a stock of celery, without any seeming repugnance."

This opinion, however, that the poison of snakes may be taken internally without producing any troublesome effects, has been recently contradicted by the experience of Dr Hering, at Surinam. This traveller took at different times various doses of the poison of a rattle-snake (*Crotalus mutus*) mixed with water, and suffered from its effects for upwards of eight succeeding days. These manifested themselves by pains in the larynx and other parts of the body, by an increased secretion of mucus in the membranes of the nose and œsophagus, and by frequent diarrhœa, accompanied by pain in the rectum. To these symptoms were added several others of a rather curious kind, attributable to the influence which this poison seemed to exercise even over the moral faculties.

By far the most deleterious effect, however, of this subtle fluid is produced by its mingling with the blood, through the medium of an inflicted wound. It then shows its morbid influence with a rapidity often frightful, and usually proportioned to the quantity of the poison instilled, and to the abundance with which the wounded part is furnished with those vessels which bear the stream of life. For this reason, of course, the bite of a large snake is more dangerous than that of a small one; and so also a wound in the tongue, or in any vein, is almost always mortal, while it not unfrequently happens, that when a hard or callous part is bitten, no injurious results are found to follow. Cold-blooded animals are much less affected by the bite of a snake than are quadrupeds or birds; and in the majority of invertebrated tribes it produces no effect whatever. Generally speaking, however, the smaller the victim, the more deadly are the consequences of a wound. In Europe, the human race scarcely ever suffers fatally from the bite of a viper; and it is supposed that the poison of several would be required to kill a bullock or a horse. So at least say many modern writers; yet we cannot help remembering what Boerhaave tells us regarding a viper, which, "being enraged by the members of the Tuscan Academy," and then suffered to bite the nose of a strong bull, the ponderous creature died in a very short time. A small quadruped dies rapidly from an infliction of the slightest wound. In tropical countries, however, where the poisonous species are often of considerable size, and their venom is both more abundant and in a state of higher concentration, the effects are fatal both to man and beast. The activity of the poison, in truth, increases with the temperature of the climate.

Various experiments have been tried, with a view to ascertain the strength of this animal poison in different species of serpents, and the best means of arresting its fatal influence. The observations of Laurentius, Fontana, Russel, Davy, and Lenz, are familiar to the student of physiology, but less satisfactory in their results than might be desired, from the modifying effects of special circumstances. To obtain well rectified general inferences, it would be necessary that numerous experiments should be tried with serpents of corresponding size, existing under similar circumstances, and in relation to victims of the same constitution; and by repeating these experiments with various kinds of serpents, and taking the average effect of each kind as a result, we might in a measure ascertain the different characters of these animal poisons, of which we have as yet but a meagre knowledge.

---

[1] See Shaw's *General Zoology*, iii. p. 371.

The effect of a serpent's bite usually manifests itself without delay. A sharp pain is felt in the part pierced by the fangs, although the puncture is extremely minute, and scarcely a drop of blood may flow; swelling follows, and inflammation soon declares itself. The progressive effects upon other parts of the system are exhibited by a general feebleness; walking becomes painful, and respiration laborious and constrained; the patient suffers from ardent thirst, followed by nausea, vomiting, glimmering of the sight, and other symptoms, which, combined with acute bodily pains, often deprive the victim of his senses. Livid spots sometimes surround the wound, the dread precursors of that fatal gangrene which, spreading more extensively, ere long puts a period to existence. "His strength is poured out like water, and all his bones are out of joint; his heart is like wax, it is melted in the midst of his bowels. His strength is dried up like a potsherd, and his tongue cleaveth to his jaws, and he is brought unto the dust of death." Then, instead of the bloom of youth, the power of manhood, or the pride of beauty, we behold but a bloated corpse, the sad repulsive remnant of humanity. It may be remarked, however, that the poison of these subtle reptiles seems to deprive us of life under a considerable variety of aspects. A lethargic torpor without pain is said to follow the bite of the asp; and hence, we presume, its preference by that luxurious queen for whom Antony "lost the world." The fact, though doubted by medical observers, seems in a great measure confirmed by the examples adduced by Captain Gowdie, as recorded by Dr Russel.[1] Lucan of old has distinguished the poisonous serpents that infested the march of the Roman army over the deserts of Libya, by the various symptoms which they produced; but his dreadful catalogue should perhaps be regarded rather as a piece of poetical embellishment than as an historical relation. Yet it seems now believed, that however the symptoms may vary, the nature and action of the poison is the same in all, and is in most cases to be counteracted by the same means. The virulence of the bite even of individuals of the same species probably varies according to the season of the year, just as their manners and external aspect also vary, as so beautifully described by Virgil.

> Postquam exhausta palus, terræque ardore dehiscunt;
> Exilit in siccum, et flammantia lumina torquens
> Sævit agris, asperque siti, atque exterritus æstu.
> Ne mihi tum molles sub dio carpere somnos,
> Neu dorso nemoris libeat jacuisse per herbas:
> Cùm positis novus exuviis nitidusque juventu,
> Volvitur, aut catulos tectis aut ova relinquens,
> Arduus ad Solem, et linguis micat ore trisulcis.[2]

The excessive rapidity with which death was frequently produced by the bite of venomous serpents, induced Dr Mead to conclude that its fatal influence affected the nervous rather than the circulating system. But the experiments of Fontana go far to demonstrate that the venom of the viper is perfectly innocent when applied to the nerves only; but that it acts immediately upon the blood, and through the medium of that fluid destroys the irritability of the muscular fibre, and so produces death. A different idea has been more recently proposed; that the poison of serpents acts upon the blood by attracting the oxygen which it contains, and which is believed to be essential to its vital functions. The human heart, and in general the heart of all animals with warm blood, has two ventricles or cavities; and the blood, before it is returned to the right ventricle, has to perform two circles, a lesser between the heart and the lungs, and a greater between the heart and the rest of the body. While the blood passes through the lungs, it undergoes a very remarkable change of colour, and of other properties. A certain portion of atmospheric air is attracted and absorbed, while the remainder carries off by expiration whatever ingredient of the blood is either unnecessary or injurious. The atmosphere we respire is a compound fluid, of which one portion is oxygen or pure air, and another and much larger is noxious or azotic air; and it is the former ingredient only which is attracted by the blood in its passage through the lungs, and contributes to the maintenance of animal life. From this combination, the heat of animals, and the brilliant colour of the blood, are supposed to be derived.

The preceding observations will enable the reader to comprehend more clearly the theory of the action of poisons proposed by Mr Boag. He adduces the following arguments in its support: 1. Man and other warm-blooded animals, exposed to an atmosphere deprived of oxygen, quickly expire. The poison of a serpent, when introduced into the blood, also causes death; but carried into circulation by a wound, and in very small quantity, its operation is comparatively slow and gradual. 2. The appearances on dissection are very similar in both cases, the blood becoming of a darker hue, and coagulating about the heart and larger vessels. The destruction of the fibrous irritability, and tendency to rapid putrefaction, are also remarkable in each. 3. Although Dr Mead mingled the venom of a viper with healthy blood *out* of the body without perceiving it produce any change in its appearance, this is presumed to arise from his having mixed a very small portion of poison with a large portion of blood; but if two or three drops of venom be mixed with forty or fifty drops of blood, it immediately loses its vermilion colour, becomes black, and incapable of coagulation. 4. It is, moreover, a remarkable circumstance, that the poison of serpents has most power over those animals in which the blood is the warmest and the action of the heart the most lively, while it is but a tardy and altogether uncertain instrument of death to the majority of cold-blooded creatures. Of this the reason is, as Mr Boag supposes, that cold-blooded animals do not require a large quantity of oxygen to preserve their lives; a fact otherwise sufficiently obvious from the conformation of their heart and respiratory organs. Fontana's experiments with a view to the prevention of the fatal effects of poison, may be here stated in a few words. He applied lunar caustic, which is a preparation of silver in nitric acid, and found on so doing, that not only was the venom thereby rendered innocuous, but the corroding power of the caustic greatly diminished. He next wounded a variety of animals by means of envenomed teeth, and scarifying the wounds, he washed them in a solution of lunar caustic and water, and by this means saved the lives of the greater number, although they belonged to species which he knew to be easily killed, while the death of others was greatly retarded. These experiments, it may be added, neither proceeded upon nor led to any theory.

Now the application of the following admitted facts is presumed by Mr Boag to explain the efficacy of Fontana's treatment, and to illustrate the accuracy of his own views. 1. Oxygen enters into the composition of all acids, and is the principle, as its name imports, on which their acidity depends. 2. Metals are united with oxygen under various circumstances, but chiefly in two ways; the first is by burning them in an open fire, or, to speak more philosophically, by the contact of heat and air, when they are converted into metallic oxides; the second is by the decomposition of acids, when they form compound salts. 3. Oxygen is attracted by different metals with different degrees of force; those which attract it with the least force are the more perfect metals, such as platina, gold, and silver, which cannot be converted into oxides, except at very high temperatures; whereas arsenic, and many other substances, attract it strongly, and are usually found in combination with it even in the bowels of the earth. If, therefore, the mortal effects which arise from the bite of a serpent result, as stated by Mr Boag, from the subtraction of oxygen from the blood, it is natural to suppose that the most efficient cure must consist in the renewal of that vital ingredient; and the most obvious and easy mode of accomplishing this will be, to employ such substances as are known to contain oxygen in the greatest abundance, and to give it up with the greatest facility. This is precisely the character of lunar caustic, which is made by dissolving silver in nitric acid, and afterwards evaporating and crystallizing the solution.[1]

---

[1] In his work on the *Serpents of the Coast of Coromandel.*

[2] *Geor.* lib. iii. l. 432.

In further illustration of this singular subject, we may here give a brief account of the effect produced by the bite of some remarkable salt-water snakes, belonging to the genus *Hydrus* (*Hydrophis* of our present treatise). Soon after the opening of the bar in the month of October 1815, reports prevailed at Madras that a great shoal of sea-snakes had entered the river, and that many natives while crossing had been bitten, and had died in consequence. A reward was offered for each of these creatures captured and carried to the superintendent of police. Pandauls were erected opposite to the two principal fords, and skilful natives, under the direction of Dr M'Kenzie (to whom we are indebted for the information), were provided with eau-de-luce and other remedies, and ordered to afford immediate aid to those who might be bitten. Many were bitten accordingly (the snakes seeming in no way loathe to expedite the result), and all exhibited the symptoms usually consequent upon the action of a powerful animal poison; but none died. We shall state a couple of cases, with the mode of treatment. A native woman, while crossing near the custom-house, was seen, on emerging from the water, to shake off something from her foot. This to several spectators appeared to be a water-snake. The woman, after advancing a few paces from the river, fell down, and was immediately carried insensible to the pandaul. On examining her feet, two small but distinct wounds were perceived on the ankle of the right leg; her skin was cold, her face livid, her breathing laborious, her pulse scarcely perceptible. A ligature was immediately placed above the wound, which had been previously enlarged with a lancet, and a piece of the carbonate of ammonia well moistened with pure nitric acid applied, while thirty drops of the eau-de-luce were administered nearly at the same time in a glass of water. In five minutes more a similar dose was poured down the throat, which seemed rather to increase the spasmodic affection of the chest; but the pulse at the wrist became distinct, though feeble. A third dose was repeated in three minutes more, on which she uttered a scream, and began to breathe more freely. Ten minutes had now elapsed since she had been carried to the pandaul, and in about three minutes more a tea-spoonful of the eau-de-luce was given, which almost immediately produced violent nausea, and a profuse perspiration. When a little salt was put into her mouth, she declared it was not salt, but sugar; and this the natives deemed an infallible sign of still-continued danger. She soon, however, entirely recovered, and merely complained for three or four days of a numbness in the limb above the wound. Another case was that of a Lascar, who was bitten by a snake while in the middle of the river. He advanced a few paces after quitting the bank, and then fell down in violent convulsions. When brought in, his breathing was laborious, his skin cold and clammy, his countenance livid, and his pulse feeble at the wrist, but distinct at the temples. A quantity of froth and foam was ejected from between his closed teeth. He too recovered, after a similar mode of treatment; but he complained for many days *that he had no left leg*. On another occasion a large healthy chicken was exposed to the bite of a *Hydrus major*, four feet long. It was bit in the foot, and in about ten minutes began to droop, and to show a slight convulsive flutter of both wings. In three minutes more it became convulsed, and at the end of seventeen minutes from the infliction of the wound it suddenly dropped down dead.[2]

Dr Russel has figured and described forty-three of the most common serpents of Hindustan, and of these he found only seven that were provided with poison-fangs. He informs us, that a quantity of warm Madeira taken internally, with an outward application of eau-de-luce on the punctures, was generally successful in curing the bite of even the most venomous species. He also states that the medicine called the Tanjore pill was equally efficacious. On comparing the effects of the poison of five of the oriental species on brute animals, with those resulting from the rattle-snake and European viper, Dr Russel remarked, that they all produced morbid symptoms nearly the same, although they might differ in the degree of their deleterious power, and the rapidity of its operation.

The tongue of serpents is remarkable for its great extensibility. It is protected by a rather firm skin, becomes very slim towards the anterior extremity, where it divides into two slender filaments, and is capable of being withdrawn into a kind of sheath, which opens in front of the glottis. The position of these parts varies in the different species, being placed, for example, very near the muzzle in the genus *Hydrophis*, but much further backwards among both the terrestrial and the tree serpents. The tongue of the Ophidians in general, though extremely similar to that of certain Saurians, such as *Monitor*, *Tejus*, and other genera, yet differs in the far greater simplicity of the harder parts by which it is supported; for we find, in place of a hyoid bone, composed of several pieces, merely a simple cartilaginous thread attached to the internal face of the general integument of the gular region, with its two extremities prolonged greatly backwards. This cartilage is sometimes, as in *Boa*, intimately united to the muscles of the throat, of which it intersects the fibres, its posterior extremity being then attached to the skin on the sides of the neck; but in the majority of cases, the horns of the hyoid are free, closely approached, and prolonged into the cavity of the chest, even as far as the heart. The tongue of these reptiles seems in truth, by its construction, to be a genuine organ of touch, and serving neither for taste nor deglutition, being during the latter act enclosed within its sheath. A little notch-like aperture at the end of the muzzle, which exists in most serpents, except the aquatic kinds, admits the protrusion of the tongue without the necessity of opening the mouth. This movement is usually made very leisurely, although with extreme rapidity when the individual is excited either by fear or passion.[3]

The use of the tongue in serpents is not exactly known. Its narrow and cylindrical form would render it unapt to aid the process of mastication, even were the teeth of a nature to perform that process. They are continually lancing it into the air, and may possibly in this way also gather moisture from grass or other herbage. It is, however, believed that they never drink. "On ignore," says M. Schlegel, "si les serpens boivent, et s'il est juste d'opiner pour la negative; toutefois on n'a jamais aperçu des fluides dans ceux dont on a examiné l'estomac."[1] Other authors, however, are of a somewhat different opinion. "Tout au plus," say MM. Dumeril and Bibron, "cette langue fort longue sert-elle, comme on l'a observé quelquefois, à faire pénétrer un peu de liquide dans la bouche, car nous avons vu nous-même des couleuvres laper ainsi l'eau que nous avions placée auprès d'elles dans la cage où nous les tenions renfermées pour les observer à loisir."[2]

[3] See Helmann, *Uber den Tastsinn der Schlangen.*

The alimentary canal of the Ophidians is remarkable for its great simplicity.[3] The œsophagus and stomach form a continuous canal, to the special parts of which it is difficult to assign precise limits. The pancreas, according to M. Schlegel, is always placed "dans la première courbure qui fait l'intestin à partir du pylore," and varies in different species both as to size and form. The spleen is of an oval or somewhat globular shape, of a rather firm consistence, and frequently concealed among the lobes of the pancreas, with which it is sometimes intimately united. The liver in Ophidian reptiles assumes a long ribbon-shaped form, more slender at either end, sometimes imperfectly divided into a couple of lobes, and extending along the œsophagus and stomach, from the heart as far as the pylorus. The hepatic canal descends from its interior face towards the pancreas, to conduct the bile into the small intestine. The gall-bladder, which is abundantly supplied, discharges its fluid by a short conduit, which joins the hepatic canal at an angle more or less acute. The kidneys, remarkable for their lengthened form and symmetrical position, are divided into a great number of small lobes, adhering to each other by means of the cellular tissue.

Digestion, notwithstanding the activity of the gastric juice, is sufficiently slow in serpents. It would appear, in fact, that the juice in question exercises its influence chiefly in the regions near the pylorus; for it has been found that an animal withdrawn from the abdomen of a snake is always decomposed towards its lower extremity, while the portion lying nearer the œsophagus continues unconsumed. Indigestible portions, such as hair, feathers, &c. are said to be sometimes ejected by the mouth; and, according to M. Dieperink, when a serpent in a wild state is pursued soon after it has swallowed a considerable prey, it will disgorge it to facilitate the means of escape. In regard to the digestive faculty of serpents, one of the most remarkable characters consists in the strong absorbing power of the intestines. When we examine their fecal remains, we find that these exhibit as it were a dry extract of the entire prey, of which the parts incapable of liquefaction remain not only unaltered, but occupying precisely the same relative positions which they held in the living animal. If, for example, a rat has been swallowed, we find, in what at first appears a dry and unformed heap, the muzzle, the long hairs upon the cheeks, the down which covers the thin cartilage of the ears, the hair, of various length and colour, which has clothed the back, abdomen, and especially the tail, and finally the nails, in a perfectly entire state. All fleshy or softer substances have been completely absorbed; and the earthy salts, which by their union with the gelatine give consistence to the bones, still indicate by their colour the position formerly occupied by these osseous portions. The most complete natural analysis has been effected by means of dissolution, compression, and absorption,—and of this the desiccated mass already mentioned is the sole residuum.[4] The infrequent meals of serpents are thus in a measure compensated by the great profit which they derive from each.

The mode in which these reptiles swallow their food is sufficiently simple. They commence by getting the head within their throat, and while the teeth of one jaw adhere to the prey, the other jaw makes a forward movement, and, fastening its teeth, draws the object inwards, till by this alternate action of the jaws, and chiefly of the under one, deglutition is effected. The jaws, as we have already hinted, are capable of a certain separation from each other even at their basis, and an abundant supply of saliva being at the same time poured out upon the victim, a body larger in bulk than the snake itself is sometimes swallowed; and as in this case the process is slow, and but a small portion can enter the throat at a time, the reptile reposes for a considerable period, even till, with distended mouth, it seems gorged with putrefaction, presenting a hideous and disgusting picture of gluttony and sloth. When the venomous kinds swallow their prey, they do not use their poison-fangs, but lower these beautiful and highly-finished instruments of destruction into the hollow of the gums,—"sheathing them as a sword."

The heart of Ophidian reptiles is usually of an elongated form, and is remarkable for its distant position from the head. It is composed of two spacious auricles, separated from each other by a membranous division; the ventricle, on the contrary, is imperfectly divided into two rather narrow cavities, by a partition which takes its origin from the base of the heart, and loses itself amid the fleshy fibres of that region. The walls of the auricle, although fleshy, are slender,—those of the ventricle are of considerable thickness, especially on the left side of that portion which extends in the form of a conical appendage beneath the left auricle. Each auricle communicates with the ventricle by means of a broadish opening, susceptible of being closed by a valve. The right auricle receives all the veins, which form, with the exception of the left jugular, prior to passing through the wall of the auricle, a kind of sac of greater or less extent, which, in addition to the ordinary tunics, exhibits a distinct muscular coat. Two large valves serve to close the common entrance of the veins into this auricle. When the blood has attained the right chamber of the ventricle, it is driven into the pulmonary artery, of which the embouchure offers two valves; comprised at its base in the common trunk of the aortas, this artery curves itself beneath the left aorta, and approaches the lung, of which it margins the posterior face before entering the interior of that organ. A single pulmonary vein, piercing the lung behind the artery of the same denomination, carries the oxydised blood into the left auricle, which is of a conoid form, and less spacious than the right one. This oxydised blood, after having passed into the left cavity, is pushed towards the right side, where we find the embouchures of the two aortas, of which each exhibits a pair of semicircular valves, even when these openings are united into one.

We shall now devote a few lines to the respiratory organs. When we observe a serpent in a state of repose,—

as on the grassy herb
Fearless, unfeared, he sleeps,—

we may see that its body alternately dilates and contracts by the play of the ribs, and that this movement is repeated slowly, yet at regular intervals. But we may also perceive, that the nostrils are closed for a longer, and consequently an unconforming period, during one of which the body is contracted and dilated perhaps thirty times. It results from this observation, that the lungs of Ophidians, besides their ordinary function, fulfil that of serving as reservoirs of atmospheric air, which, though replenished only by a single inspiration, contain a quantity sufficient to admit a continuous oxydation of the blood by the contraction of the lungs. When the oxygen is totally absorbed, expiration takes place, and a supply of fresh air is drawn in. The configuration of the lungs undergoes many modifications in the different races of Ophidian reptiles. The form is usually that of a simple conical sac, extending from the heart toward the lower regions of the stomach, where it ends in a membranous pouch. The trachea, composed of numerous demi-rings united anteriorly by a membrane, terminates in the origin of the lungs by an oblique opening. The latter organ is divided more or less completely into two bronchiæ in *Boa*, the majority of *Tortrix*, the genus *Dipsas*, and others; and in these we may perceive the vestige of a second lobule of the lung, sometimes half as large as that on the other side. A singular peculiarity is observable among the sea-serpents. In *Hydrophis colubrinus*, for instance, the tracheal pipe is prolonged into the hypochondriac region, where it terminates in a membranous sac, extending to within a couple of inches of the anus; but in place of a membrane uniting the rings of the trachea, it is the lung itself that envelopes that tube throughout its whole length.

[2] *Erp. Gen.* i. 135.

[3] The digestive organs are described by Duvernoy in *Ann. des Sciences Nat.*, and by Meckel in his *Vergl. Anat.*

[4] *Erp. Générale*, i. 145.

The small size of the brain in serpents is obvious in all, and becomes very conspicuous in relation to the size of the head, when we select for observation any of those species in which the organs of manducation are strongly developed. The two hemispheres are prolonged by restriction into the olfactive lobule, so that the latter part is borne, as it were, upon a pedicle. We observe the optic lobules on their posterior face, and passing beneath the hemispheres towards the eye, to form the optic nerve. The cerebellum is a very small organ, situate behind the optic lobules, almost uniform with the spinal cord, or offering but an inconsiderable enlargement. The grand sympathetic nerve is interlaced at so many points with the par vagum, that it is next to impossible to trace its origin with any certainty.

As to the intellectual faculties of these reptiles, we know that Satan found

> The serpent subtlest beast of all the field;

and we doubt not that, even in our own days, they may be placed at least upon an equality with the Saurian and Chelonian orders. The reproductive power with which their separate parts are said to be endowed has probably been the subject of some exaggeration; and it seems certain that when the tail or other important portion has been destroyed by mutilation, it is altogether incapable of being reproduced. The sense of smell is believed to be by no means acute in these reptiles. The nostrils vary in the different genera in respect to form, size, and position. It may, however, be stated as a constant rule, that the purely aquatic species have the nostrils small, directed upwards, and for the most part susceptible of being closed by means of a valve, while those of the terrestrial and arboreal kinds are usually lateral and open. Among the burrowing serpents these openings are almost always of an orbicular form, and of very small dimensions. In the genera *Trigonocephalus* and *Crotalus* there is a cavity on each side of the muzzle, behind the nostrils, of which the use is still unknown. The eye is probably defective in the power of distant vision, though sufficiently acute for all the ordinary purposes of a serpent's life. It is covered over by the external skin, of which, however, the tunics are in that quarter extremely thin and diaphanous, and present themselves under the form of a hemispherical lamella adhering to the scaly plates which surround the orbit. There is thus no apparent eye-lid to the visual organs of serpents, a slight edging of the skin forming their only protection.[1] The supposed absence of this part was presumed by the ancients, and has been recorded in the writings even of modern anatomists of the greatest skill. But more recent researches, undertaken by M. Cloquet, and verified by Baron Cuvier and M. Dumeril, have demonstrated that the eye of Ophidians is covered by a single lid, large though immoveable, and incased in a projecting frame, which forms around the orbit a series of scales, variable in number, though usually amounting to seven or eight. When the general covering is renewed, we find that a delicate coating of the eye is likewise thrown off as a portion of the exuviæ. The structure of the ear in serpents seems to demonstrate that these creatures are dull in their sense of hearing.

The general envelope of Ophidian reptiles forms a kind of cuirass, which enables them to withstand the influence of the elements and the effects of external accidents. To conform to the movements of the body, and the occasional enlargement of its parts, this covering, we need scarcely say, is composed of a multiplicity of separate compartments, of which the smaller are called scales, the larger plates. These parts are composed of much thicker layers of the integument than the intervening portion, which consists of a delicate skin, seldom visible except when the body is more than usually distended, and for this reason almost always colourless, being unsubjected to the influence of light. In certain species of the genus *Tropidonotus*, however, the mucous membrane of the neck is so tinted as to exhibit a beautiful vermilion-red between the scales; and the scales themselves in many species exhibit colours, both fixed and iridescent, of great brilliancy:—

> With burnished neck of verdant gold, erect
> Amidst their circling spires.

The general tinting depends in a great measure upon the condition of the epidermis, and is always freshest and purest immediately after the casting of the slough or superficial skin. The total amount of longitudinal rows of scales is almost always an unequal number, there being a single range rather larger than the rest along the centre of the dorsal region, with an equal number on either side; but to this rule *Herpetodryas carinatus* forms an exception (the only one perhaps throughout the order), there being a double central row of scales along the back. The form of the scales is greatly varied, some being rounded on the margins, others truncated at the extremity, or prolonged into a sharpish point. The greater number are what naturalists call *imbricated*, that is, lying slightly over each other like the tiles of a house; but almost all sea-serpents have the scales of a hexagonal form, with the epidermis very thin.

The median line of the lower parts is usually covered by a range of broad scaly plates, of much larger dimensions than the ordinary lateral and dorsal scales; and the caudal plates are generally different from those of the abdomen. The latter form a single uniform range from the anus to the throat, where they disappear. They are sometimes narrow, as in the genera *Boa*, *Tortrix*, &c., and in such cases resemble the scales of the back; but in the far greater number they are so broad as to encroach even on the flanks, and thus occupy a large proportion of the circumference of the body. The plates beneath the tail do not form a single central range, except in *Boa*, *Eryx*, and a few other Ophidians, the majority of the order having the part in question provided with a double row of plates. We may add, that the terminal plates of the abdomen also not unfrequently partake of this divided character.

The head of Ophidian reptiles is rarely clothed with scales of a character similar to those of the body. They are larger, and of a more determinate and symmetrical form; and as they offer distinctive characters of easy application, they have received from M. Schlegel various names, in accordance with the position they occupy, such as vertical, occipital, superciliary, frontal, rostral, labial, ocular, frenal, temporal, mental, and gular.[1]

---

[1] " Nous avons dèja dit qu'il n'y avait pas de paupières apparentes dans les serpens, et que ces animaux semblent, par cela même, avoir l'œil fixe, et être toujours éveillés." (*Erp. Gén.* i. 102.)

The system of coloration which prevails among these insidious creatures is very varied, and admits of numerous exceptions to any general laws which we might attempt to establish in its illustration. In numerous species there is a beautiful accordance between the tinting of the body and the colour of the places they inhabit; thus many tree-serpents are of a uniform greenish hue, exactly similar to that of the foliage by which they are overshadowed, while several kinds of *Dendrophis* and *Dryophis* seem rather to imitate the small and leafless branches. In the genus *Dipsas* the colours recall to mind those of the mossy trunks of ancient trees; fresh-water snakes are usually of a sombre uniform hue; while the marine species partake of those clearer tints of green and blue which beautify the pellucid billows of the up-heaving sea. Such as dwell in dry and desert lands are often to be scarcely distinguished from the parched sand by which they are surrounded; while others, which affect a more varied soil and richer vegetation, are adorned with the gay and gorgeous colouring of flowers, or the metallic splendour of the mineral kingdom. Several have their bodies encircled by alternate bands of crimson and black upon a pearly-white or delicate yellow ground, and present an aspect as richly adorned as any we can discover throughout the entire range of the animal world.

> Lovelier not those that in Illyria changed
> Mermione and Cadmus, or the God
> In Epidaurus, nor to which transformed
> Ammonian Jove, or Capitoline was seen :
> He with Olympias, this with her who bore
> Scipio, the height of Rome.

Among the more beautiful may be mentioned *Coronella venustissima* and *coccinea*, *Lycodon formosus*, several species of *Tortrix* and *Heterodon*, the majority of the genus *Elaps*, *Naja lubrica*, *Dendrophis ornata*, and *Dipsas macrorhina*. Numerous other species are equally remarkable, both for the splendour and diversity of colour by which they are adorned; but as these bright hues are subject to numerous causes of variation, from age, sex, and season, it results, that among no order of created beings is the always uncertain character of colour to be less depended on than among the subjects of our present dissertation. It seems, however, established as a general law, that the younger individuals have the liveliest and most distinct tints, and that these in more aged examples are not unfrequently effaced, or fade away, as we find in *Coluber canus* and *melanurus*, *Homalopsis buccata*, *Xenodon severus*, and others. The power of speedy and spontaneous change of colour does not, however, seem to be a possession of the Ophidian order, as it is of so many of the Saurian tribes. Yet a few of the arboreal serpents have been occasionally observed to modify their living tints from time to time.

The natural colours of these creatures can scarcely be judged of from specimens imported to our cabinets from foreign climes. The spirit in which they are preserved is not the spirit of beauty. Black, brown, ochry-yellow, and several other tints, do not altogether lose their lustre; and *Calamaria arctiventris* and *brachyorrhos*, *Tortrix maculata* and *xenopeltis*, *Coronella rufula*, *Lycodon hebe* and *subcinctus*, *Coluber constrictor*, *Æsculapii*, and *melanurus*, and several kinds of *Naja*, *Homalopsis*, and *Vipera*, may be named among those which are most easily preserved. But green speedily tarnishes after death, loses its vivacity, and becomes bluish; it even communicates its tint to spirit of wine. White almost always loses its purity, and becomes of a soiled or yellowish aspect, while pale yellow passes into dingy white. The brilliant hues of red and orange with which so many species are adorned, almost entirely disappear, and are converted into dingy or brownish yellow. Blue, which is rather a rare colour among Ophidian reptiles, also quickly fades away, and the more exposed the specimens are to the influence of light, the more rapidly are these and other changes effected.

In discussing the various branches of natural history, it is the practice of authors to state the *uses* of each particular tribe of animals to the human race. We fear, that in relation to our present subjects, a single paragraph may suffice. Serpents certainly confer benefit by destroying other injurious creatures, such as small mammiferous vermin, worms, insects, and mollusca of various kinds. They were formerly used in medicine, though that practice, we believe, is now confined to the ignorant and superstitious; yet it has been recently stated, that Dr Marikrosky, of Rosenau, in Hungary, has employed the gall of serpents with success in epileptic cases.[2] It is well known that the flesh of the viper has been highly esteemed, both by ancient and modern physicians, as a restorative and strengthening diet. This idea, as Dr Shaw has well observed, seems to have originated from the reptile casting its skin, a natural process, viewed by the vulgar as a renovation of youth; and a snake being made the emblem of health, and consecrated to Æsculapius, may have depended on the same idea. The flesh of the viper was used by the ancients in leprous and other cases. "The Greek physician Craterus, mentioned so often by Cicero in his Epistles to Atticus, cured, as Porphyrius relates, a miserable slave, whose skin in a strange manner fell off from his bones, by advising him to feed on vipers' flesh in the manner of fish. Antonius Musa, physician to Octavius Cæsar (Augustus), is said by Pliny to have ordered the eating of vipers, in the case of otherwise incurable ulcers, which by this method were quickly healed; and Galen says, that those who are afflicted with elephantiasis are wonderfully relieved by eating vipers' flesh dressed like eels."[3] According to Lopez, the negroes of the coast of Congo eat roasted adders, and regard them as delicious food. It is well known that the credulous Sir Kenelm Digby, with a view to recover his wife, the Lady Venetia, from consumption, caused her to feed on capons fattened with vipers. But we need not detain our readers with more of these, at best, ambiguous views. To proceed with our natural history.

In European countries, the copulation of serpents usually takes place, in fine weather, during the months of April and May, and three or four months elapse before the eggs are laid. Incubation is effected within the body of the female; for, on opening an egg immediately after exclusion, we almost always find a fœtus more or less developed, sometimes entirely formed. In the latter case, the so-called shell is merely a delicate membrane, through which the young can force their way, even at the moment of parturition. In the greater number of species, however, the eggs are composed externally of a resistant covering resembling parchment, the young being very imperfectly formed at the period of deposition, and requiring sometimes a month or more before they are hatched. It is merely this difference in the times of final exclusion that constitutes the distinction between the viviparous and oviparous kinds, these being otherwise essentially the same. All Ophidians are in truth oviparous; and those naturalists are in error who compare this seemingly viviparous generation to that of mammiferous animals, in which the young are nourished by the placenta of the mother. According to M. Herholdt,[4] the conditions most favourable to the development of these embryons are humidity, produced by a feeble vegetable fermentation, with a proportional temperature (between + 20° and + 6° R.), and under circumstances likely to favour absorption and evaporation through the external tunic of the egg. Hence their love of dunghills, or heaps of leaves piled up in places open to the sun.

---

[3] *General Zoology*, iii. 372.

[4] *Oversigt.* 1830, p. 4.

The supposition entertained by many is incorrect, that poisonous serpents always produce living young, and that the innocuous kinds as constantly deposit eggs. This diversity in the generative process does not seem to bear any relation to the organization of the species; at least we find the two modes exemplified in nearly-related species of the same genus. Thus the harmless *Coronella lævis* produces young as lively as those of the common viper; *Boa murina* is also viviparous, while the deadly *Najas* and several others lay eggs. The number of young ones varies in different species. M. Schlegel did not find above ten in several kinds of *Calamaria*, from twenty to twenty-five in the genus *Coluber*, and above thirty in *Trigonocephalus atrox*. The offspring usually differ from their parents in being of more lively colours, with the head blunter and rounder, the eyes larger, and the scales and other appendages of the epidermis less raised. They are, however, furnished with teeth exactly like those of their respective parents, and of which they do not fail, when occasion offers, to make speedy use. The venomous kinds instinctively elevate and depress their poison-fangs, as if ready from the first to defend themselves against that persecution to which their race is subjected. The European kinds are known to change their skins about five times every summer, that is, once a month from the end of April to the beginning of September. They are capable of long-continued abstinence, independent of the lethargic state into which the northern species fall in winter. A *Boa constrictor* sent from Surinam to Holland fasted continuously for six months. The age to which serpents attain is to us unknown.

We shall now devote a few pages to a branch of our subject of peculiar interest, which we have seldom altogether neglected in relation to other departments of zoology in the course of the present work, and which, so far as concerns the singular beings now under more particular consideration, has never been at all discussed in any work accessible to the English reader,—we mean the distribution of serpents over the earth's surface.

A knowledge of the geographical distribution of reptiles may be regarded, not only as highly interesting in itself, but as extremely important in relation to the general subject of the location of organized life. Numerous diversifying agents tend to alter the original position of plants. Their seeds are carried hither and thither both by winds and waves, the human race have transported them to and from many distant regions, and artificial culture has so changed their natural characters, that the very earth which bore them can no longer recognise her offspring. A vast majority of living beings are created with the means of transporting themselves, with more or less facility, from one country to another. Many quadrupeds are continually extending the sphere of their original habitation; birds of powerful flight wing their buoyant way from clime to clime; while the liquid depths of ocean offer a vast continuous space, within which the finny tribes may exercise their migratory movements. But it is far otherwise with the race of reptiles, especially the footless tribe of serpents. Destitute of the power of long-continued locomotion, they never attempt to travel far from the places of their birth, and thus, even in our own days, they still represent more accurately than do the other classes of the animal kingdom the positions in which they may be supposed to have been originally placed. Such as inhabit northern countries, and are at the same time incapable of enduring cold, having no power to flee from the rigours of winter, escape its effects by falling into a state of lethargic repose.

It is obvious, then, that the geographical distribution of serpents presents a peculiar interest, inasmuch as it tends to make us acquainted with the true and natural relations which exist between these creatures and the places they inhabit, and thus in a measure presents us with a picture of the primitive state of matters, before man's intermeddling, and other supervening agents, had altered the local relations of animal life.

One of the most curious general facts in the distribution of serpents, is their apparent absence (at least so far as the land species are concerned) from the numerous islands of the vast Pacific Ocean,—a circumstance not altogether to be accounted for by the isolation of these various groups, seeing that those of the Indian Archipelago particularly abound with serpents. Another fact seems still more firmly established, that the reptiles of the New World are all specifically different from those of the Old,—a peculiar feature in the history of their class, in so far as many quadrupeds and birds are common to both countries. At the same time it may be borne in mind, that it is only the species of very northern portions of the two continents which are in any case identical, and that as these northern portions are almost, if not entirely, destitute of reptile life, the field is greatly narrowed, so far as that form of existence is concerned. The snakes of South America are in general very distinct from those of the northern portions of the New World, although a few are identical. Several of the southern species inhabit the West Indies and the warmer parts of the United States, where they form what may be termed *climatic varieties*. Other species more characteristic of a large extent of North America, reach as far south as Mexico and the Antilles. America in general, especially its equatorial districts, is almost as rich in snakes as the Indian islands. It is otherwise with New Holland, where these reptiles are by no means numerous, but where the species, excepting perhaps a few of its more northern kinds, are peculiar to the country. The serpents of Japan seem, without exception, to belong to particular species not hitherto observed in other quarters of the world. The numerous islands of the great Archipelago of the Indian Ocean produce in several instances identical species, and these, moreover, are not unfrequently the same as those of Malacca, Bengal, Hindustan, and Ceylon. If we may judge from the few known species, the serpents of Madagascar may be regarded as peculiar to that vast island. Africa, compared with other great equatorial continents, cannot be said to be very rich in these reptiles. Its southern portions produce species entirely different from those of Europe and of other countries; but these species have a wide range in Africa itself, being in many cases spread over all its intertropical regions, and even its northern parts. These comparatively northern countries, in addition to some peculiar species, produce several others which likewise inhabit the shores of both sides of the Mediterranean. Many of our European serpents are found over a large portion of temperate Asia,—a region which appears to produce but a small proportion of peculiar species.

The geographical distribution of families and genera,—these being viewed as representing various leading forms,—affords an equally curious subject of observation. We may notice, in the first place, that the venomous sorts are distributed, with the exception of a few islands, over whatever countries produce serpents of any kind. These venomous species bear no determinate co-relation, as is often supposed, to intense heat; for they occur in cold and temperate countries equally with the innocuous kinds. But their aggregate number is much more limited than that of the latter; for while we reckon the total number of known Ophidians at 263,[1] we do not find above fifty-seven of these endowed with injurious attributes,—that is, the proportion is not much more than one to five. This proportion, however, is not maintained throughout the various countries of the globe,—the venomous kinds seeming to be comparatively more numerous in open sterile countries. Of this, Africa and New Holland furnish examples,—the venomous species of the former continent being to the innocuous kinds as one to two or three, while of the ten species (or thereabouts) of ascertained New Holland species, not fewer than seven are venomous. In general, the number of individuals of each species is much more limited among the venomous kinds, as these live in an isolated manner, and rarely multiply so as to become abundant. Local circumstances sometimes favour an exception to this rule, as in the case of the *Trigonocephalus lanceolatus* of Martinique and St Lucia, and that of the Dalmatian *Viperus ammodytes*. The sea-snakes, all of which are poisonous, are likewise of a gregarious nature.

Excepting the anomalous group called *Tortrix*, there does not seem to exist any genus of serpents which is spread over all countries capable of maintaining reptile life; and this restriction seems to illustrate the intimate relation which subsists between the organization of these beings, and the countries they inhabit. For example, the Colubers properly so called, which are destined to dwell in countries which are either well wooded, or marshy with abundant vegetation, have not yet been observed in New Holland, and are so rare in South Africa that only a single species has been found there, and that of a somewhat anomalous nature, in so far as its characters exhibit an approach to those of species which dwell by preference in sandy deserts. A similar observation applies nearly to the genus *Coronella*, composed of species which inhabit marshy plains, or such as are covered by brushwood. None of these occur in New Holland (which is noted for its frequent want of water), while the South African kinds differ from the typical species of the genus. The *tree-serpents* are characteristic of equatorial countries, inhabiting of course only those portions which fulfil the conditions of their existence, that is, are well wooded. The three genera which compose the family are found both in the Old and New World; but it is noticeable that the species of the genus *Dipsas* of America do not attain to so great a size as the majority of those of India; while the genus *Dryophis* in America forms a true geographical division of the group, in so far as the dental system and muzzle are less developed, and the pupil of the eye is orbicular. The fresh-water snakes, comprised in the genera *Tropidonotus* and *Homalopsis*, occur abundantly in countries rich in permanent lakes, and watered by continuous rivers. They are thus well known in Asia, America, and even Europe, but are extremely rare in Africa, and unknown in New Holland. The genus *Homalopsis*, indeed, which contains the essentially aquatic species, does not occur in Africa, but predominates in the New World, so rich and unrivalled in its mighty reservoirs of water.

The geographical distribution of the *Boas* exhibits some facts worthy of record. The whole are peculiar to warm countries. The genuine species are confined to South America; their analogues in the ancient world being the *Pythons* of India, although in the latter country we also find several serpents very similar to Boas, but of very small size, and of which none exists in the western world, except a single representative in the island of Cuba. The genus *Acrochordus* forms a limited group, entirely confined to the East Indies. Of the venomous serpents, it is chiefly the vipers, and perhaps a few rattle-snakes, which make their way into temperate or colder countries, the majority of the genera occurring in intertropical regions. Of the colubriform venomous serpents, the genus *Elaps* is the only one which occurs in both worlds; and it is not improbable that the American species will be found to constitute a geographical group, distinguished by their peculiar coloration, and certain small distinctions even in form. The Indian species of the genus last named are longitudinally striped, instead of being ringed with red and black, while those of New Holland present some anomalous features. The genus *Bungarus* is proper to the East Indies, where also are found certain *Najas*, although the majority of these prefer a drier and more sandy soil,—a circumstance which explains their greater predominance in Africa and New Holland. The fact does not seem to admit of easy explanation, that *salt-water serpents* should be found almost exclusively in the Indian seas, from Malabar to the great Pacific Ocean. In regard to the venomous kinds properly so called, of the three genera of which that division is composed, it may be observed, that one, *Viperus*, is proper to the ancient world; that another, *Crotalus*, is confined to the new; while a third, *Trigonocephalus*, occurs in both. These last-named reptiles dwell in great forests, or in well-wooded countries, and for that reason are not observed either in Africa or New Holland, where they are replaced by vipers; but it may be mentioned, that the viper of New Holland is an anomalous species, while such as inhabit Europe equally depart from the typical form, and tend towards that of *Trigonocephalus*. In the genus just named two divisions may be established, one composed of species with the head clothed with scales, and which inhabit more particularly tropical countries; another formed of species with the head covered by scaly plates, and which extend into temperate regions.

The preceding are a few of the most general facts in the distribution of Ophidian reptiles. We shall now notice some of those peculiarities which distinguish particular continents,—and, first, of Europe. We here find no species of the genera *Calamaria*, *Heterodon*, or *Lycodon*, no genuine tree-serpents, no species of *Homalopsis* or *Boa*. We never meet in Europe with any salt-water serpents, nor with any of the colubriform venomous kinds; and the poisonous tribes in general are represented merely by a few vipers. That the entire order of Ophidian reptiles has its great centre of dominion in sultry regions, is made manifest by the fact,

---

[1] We here follow the computation of M. Schlegel, who probably proceeds upon the idea that the actual species have been nominally multiplied by the misapplication (and duplication) of various names. The amount must have been considerably greater in M. Humboldt's opinion, as that illustrious writer incidentally states that equatorial America produces 115 serpents out of the 320 which form the Ophidian order. Daudin, even in his time, described about 313 supposed species, of which eighty were regarded as venomous and 233 as innocuous, which gives a greater proportion to the former than they are at present entitled to. Nearly 400 different kinds of serpents are believed to exist in the Paris Museum, although we know not with what degree of critical accuracy that enumeration has been made.

We do not ourselves possess the means of ascertaining the total number of reptiles now known to naturalists; but the following table exhibits the amount (as in 1834) in the National Museum of Paris, compared with the number described in the works of three principal writers on the class in question :—

	Lacépède, 1790.	Daudin, 1805.	Merrem, 1820.	French Museum, 1834.
Chelonians	24	62	62	97
Saurians	56	88	83	168
Ophidians	172	315	348	391
Batrachians	40	91	87	190
	292	556	580	846

We may conclude this note by observing, that the unfortunate Wagler, in his *Naturliches System der Amphibien*, four vols. Munich, 1830, with folio Atlas of plates, has described no fewer than 248 *genera* of the reptile race.

that the temperate and northern parts of Europe produce no peculiar species, that is, no species which do not occur equally, if not more abundantly, in the southern districts of the continent, where we likewise find several kinds native to the neighbouring countries of Asia and Africa. Limits, however, may be assigned to several species, and this circumstance naturally gives rise to some curious observations. The common viper, for example, inhabits all the central parts of Europe, and is even spread over temperate Asia as far as Lake Baikal. It is well known in Sweden, spreads westwards into Britain, is frequent in Jura, Islay, and some others of our western islands, but is unknown in Ireland. The western boundary, however, of the great mass of individuals of this species may be stated to be the river Seine, while the Alps appear to form its southern limit.[1] In the southern portion of western Europe our viper is replaced by another species called the aspic (*Vipera aspis*), which spreads from Trieste over Italy into Sicily, through Switzerland and over France, passing beyond the Seine towards the Pyrenees, and probably into Spain. The southern parts of the east of Europe produce a third species of this genus, *Vipera ammodytes*, which we find to spread from Styria as far as the south of Hungary, and into Greece, Dalmatia, Sicily, and probably likewise Calabria. This distribution of so nearly-allied species seems modified by, if not dependent on, the nature of the territories which each inhabits. The first prefers, in general, heathy lands and places of a rather moist and wooded character, the second affects a dry and arid country, while the third rejoices in a rocky region. No local or climatic varieties of these vipers have been yet observed; but it is otherwise with several other snakes, which have a widely extended distribution over Europe; for example, *Coronella lævis*, and *Tropidonotus natrix* and *viperinus*. These species, of which the former two inhabit almost the whole of northern and central Europe, the last not extending further than the fiftieth degree of north latitude, occur equally in the south of Europe, where they form well-marked local varieties. Thus, in Spain, *Trop. viperinus* has the back longitudinally rayed; and a corresponding character occurs in Sardinia in relation to a species common in that island, while the Sicilian individuals present some slight additional disparities. *Coronella lævis* forms in Italy a peculiar climatic variety, of a paler hue than usual, which extends as far north as Marseilles. *Coluber Æsculapii*, which inhabits the south of Germany, is also found in Dalmatia, Italy, and Provence. *Col. viridiflavus* has been observed over all the south of Europe, Greece, Hungary, Dalmatia, Italy, Sicily, Sardinia, and as far north as France and Switzerland. *Col. hippocrepis* occurs in Spain and Sardinia, while *Col. leopardinus* is a native of Sicily, Dalmatia, and Greece; but, so far as known, neither of these kinds is met with in Italy. Neither has *Psammophis lacertina*, so common in Dalmatia, in Spain, and a large portion of France, been ever found either in Italy or the adjacent islands. The southern countries of Europe produce several serpents which are not characterized by a great extent of distribution. Such are *Xenodon Michahellis* of Spain, and *Psammophis Dahlii* of Dalmatia (the latter, however, which approaches the tree-serpents in its slenderly elongated form, being found also in Greece), and *Tortrix eryx*, confined to Greece as a European species, but elsewhere well known amid African and Asiatic deserts.

A careful and more extended study of the distribution of animal life in Africa would be found to illustrate many curious relations both in descriptive zoology and physical geography. No other continent furnishes more striking proofs of the connection between the natural characters of a country and its animal inhabitants. Thus, after acquiring some knowledge of the physical constitution of Africa, we might almost predicate the prevailing features of its natural history. The leading character of this continent is the presence of vast sandy plains or deserts, and elevated plateaus, of which the vegetation is either entirely extinguished, or held by a precarious tenure. Acted upon continually by a burning sun, the flat unvaried surface is altogether unfit for the production of those vapours which, in a state of atmospheric condensation, produce our refreshing showers of frequent moisture, and the more stormy accessories of hail and snow. The great mountain ranges being few and far between, the intermediate regions possess no perennial fountains of refreshing water, no "clouds of morning dew," to clothe their arid wastes with verdure. Hence the absence of that mighty power which in America slumbers amid the most unpeopled wilderness, and makes, when aided by the hand of man, the "desert blossom as the rose." It results from the fact of so large a portion of Africa being destitute of rivers, and consequently of forests and other lowlier vegetation, that we there find but a small number of those animals which inhabit woods and fresh waters, while such as are fitted to scour over vast plains occur in great abundance. Hence the absence of stags and the existence of vast troops of antelopes; hence also the scarcity of squirrels and other wood-haunting Rodentia, and the increase of certain swift-footed terrestrial kinds. The characters of reptile life exhibit an equal conformity with the spirit of these observations. Africa produces perhaps a greater number of land-tortoises than all other portions of the world combined; but the fresh-water kinds, with the exception of a single *Emys*, and one or two species of the genus *Trionyx*, are nearly unknown, while frogs and toads are also few in number. The same observation applies in reference both to the aquatic serpents and the wood-loving kinds. The genera *Dryophis* and *Homalopsis* are entirely wanting, and not more than one or two species are known of each of the genera *Dipsas*, *Dendrophis*, and *Tropidonotus*. In so vast a continent, however, in spite of its prevailing character of aridity, there must be numerous exceptions; and we know how far-flowing are the waters of the Nile and the Niger, how lofty and continuous the mighty mountains of Abyssinia. Many an umbrageous river, we doubt not, still rolls its crystal waters directly towards the all-absorbing sea, or fills up the glassy depth of unimagined lakes, whose beautiful shores are haunted by many unknown forms of existence,—

> Fair creatures, to whom Heaven
> A calm and sinless life, with love, hath given.

Our knowledge of African snakes, however, is still insufficient to admit of any accurate geographical sketch of their distribution being laid before our readers, for we have no data on which to assign limits to the majority even of the best-known species. Egypt and Abyssinia, Algiers, a part of Senegambia, the coast of Guinea, and the Cape,—these are the chief points from which any precise knowledge has been derived. Yet we may hazard the assertion, that Africa in general is much poorer in reptiles, particularly serpents, than either Asia or America. The number of genera is equally circumscribed; and the same observation applies to our present class as has been made in relation both to the higher animals and plants of Africa, to wit, that the species of certain genera are very numerous, and that several different kinds often inhabit the same places. Towards the southern extremity of the continent we meet with four species of the genus *Coronella*, as many of the genus *Naja*, and three *Vipers*. The other genera which

---

[1] It is indeed alleged to have been met with, though sparingly, in the valley of the Po, and as far as the Florentine territory.

Ophidian Reptiles.

occur there have each only a single representative. These reptiles belong almost without exception to species peculiar to the African continent. *Lycodon Horstokii* and *Naja rhombeata* occur on the coast of Guinea, which produces likewise *Psammophis moniliger*,—but a local variety, resembling that which is found in Egypt. In Senegambia we find three species of tree-serpents, of the genus *Dendrophis*, which differ from those of the Cape, but of which one (*Den. picta*) is spread over a vast extent of the Asiatic world, as far south-eastwards as New Guinea. The intertropical countries of Africa produce *Python bivittatus*, characterized by an equally great extension, as it is found both in Java and the Chinese empire. *Viperus arietans* of the Cape is found as far north as Abyssinia, where it forms a variety of a paler hue. Northern Africa produces several serpents of species different from those of other parts of that continent. Such are *Tortrix eryx* and *Vipera echis*, which elsewhere inhabit as far south as Hindustan,—the *Cerastes*, a species of *Dipsas*, and several kinds of *Coluber*. Other species, such as *Naja haje* and *Psammophis moniliger*, differ more or less from their southern representatives. The Mediterranean countries of Africa nourish several kinds which occur in the south of Europe; and this analogy between the two continents is very striking when we compare, not the serpents alone, but the zoological productions in general, of Barbary, with those of Portugal and Spain. No serpents have been yet observed in the islands situate within the radius of Africa, and it appears certain that they do not exist in the Canary Islands.

The great island of Madagascar, of which the natural productions are as yet but slightly known, appears to be zoologically allied to Africa chiefly by the species of its western side; and although the eastern slopes of its great mountain chain exhibit features of an Asiatic character, its totality presents a very distinct and peculiar complexion. With the exception of *Tropidonotus schistosus*, all the known serpents belong to particular and elsewhere undiscovered species. For example, the *Lanhaga*, an anomalous and very remarkable species of *Dryophis*, *Herpetodryas Goudotii* and *Rhodogaster*, and *Dipsas Gaimardii*, are all peculiar to Madagascar. The Mauritius produces a very beautiful species, *Coluber miniatus*, and a small Boa (*B. Dussumieri*) of an extremely attenuated form. From the Seychelles Islands we know of no serpent but a species of the genus *Psammophis*.

With the exception of its two magnificent Indian peninsulas, Asia is not so productive as might be expected of the reptile race. The temperature of a vast portion of the loftier and central, and *a fortiori* of the northern districts, is subjected to a low temperature during many months of the year. We know that Northern Asia, Siberia more especially, produces several animals of the higher orders, identical with some which inhabit the more rigorous parts of Europe; but the alleged identity of the Siberian species of *Tropidonotus* and *Viperus* may possibly require confirmation. A curious Ophidian, peculiar to the southern countries of Siberia, is *Trigonocephalus halys*, intermediate organically between the vipers of Europe and those species of its own genus which have the head furnished with scaly plates. The deserts to the south of the Caspian Sea, which are prolonged on the one side into Hindustan, on the other by means of the Iran, into Arabia and Syria, thus connecting with the desert tracts of Africa, produce a few species common alike to corresponding portions of both continents. We are still in almost total ignorance of the snakes of the great plateaus and other portions of Central India.

The reptiles of Japan present this peculiarity, that while the Batrachian and Chelonian orders exhibit several species identical with those of Europe (*Rana esculenta* and *temporaria*, *Hyla arborea*, *Emys vulgaris*, &c.), the Saurian and Ophidian groups seem to consist of species altogether unknown in Europe. However, we know as yet but in part, for the Japanese species hitherto collected comprise, in addition to the genus *Hydrophis*, merely three species of *Coluber*, two of *Tropidonotus*, and a single *Trigonocephalus*.

The island of Ceylon, though not extremely remote from the coast of Coromandel, produces several serpents not known in continental India, such as *Tortrix maculata*, *Calamaria scytale*, *Lycodon carinatus*, and two species of *Trigonocephalus*,—*Trig. hypnale* and *nigromarginatus*. It is along the Ceylonese shores that we first perceive certain species of the genus *Hydrophis*, those singular snakes which dwell exclusively in the sea, and occur from the island in question over all the intertropical marine waters east of Malabar, and as far as Polynesia. The number of Ophidian species which inhabit the Gangetic Peninsula, without spreading into the great islands of the Indian Archipelago, is limited. Such, however, are *Tortrix eryx*, *Coronella Russelii* and *octolineata*, several species of *Coluber* and *Lycodon*, *Dipsas trigonata*, several kinds of *Tropidonotus*, *Elaps trimaculatus*, and some vipers. The great islands themselves, with their smaller dependencies, are regarded by M. Schlegel as presenting a most interesting field for the study of zoological geography, and the observation of those local races, constituted by the diversities observable in apparently identical species placed in different localities. These islands are of the first rank as to size, situate within the tropics, covered by an abundant vegetation, and inhabited by innumerable tribes of living creatures of every class and kind. They are separated from each other by seas of no great breadth, yet sufficient to present, as matters are now constituted, an insurmountable barrier to the migration of the majority of species. Now when we find the same creatures inhabiting many different and distant islands having no communication with each other, we may reasonably infer that each insulated tract of land has borne its own inhabitants since the relations of our earth's surface became as they now exist, and that the individuals of each species form in every island a family group, which will exhibit, when compared with the corresponding species in other islands, certain modifications produced by the disparities of their position. Experience has proved the accuracy of this assumption. It has not unfrequently happened, that the same species has been discovered to inhabit Sumatra, Java, Borneo, Timor, the Celebes, the Philippine Islands, and continental Asia, and in each locality has been observed to present some constant though extremely slight distinction. Now it would never do to regard these as so many distinct species. They are only local or climatic varieties, the origin of which may be obscure or incomprehensible (as are many things besides), but which we doubt not would show their identity, by each recognising the individuals of their kind, and by breeding together, could they be transported from one to another of their sea-girt isles. Innumerable examples of these climatic differences might be adduced, were we to extend our observations throughout the vast range of the animal kingdom; but here a few examples from the reptile races must suffice. The *Najas* from the isles of Sunda constantly differ in several characters from those of Bengal and the Philippine Islands. *Tortrix rufa* from the Celebes is distinguishable from individuals of the same species from Bengal and Java, by the uniform tint of the back, and by two small spots upon the occiput. *Calamar oligodon* of Java exhibits in Sumatra a difference in the dorsal tinting, and forms in Ceylon and the Philippine Islands a third local variety of great beauty. Analogous differences exist between the individuals of *Coronella baliodeira* of Java and Sumatra. *Lycodon hebe* of Java is smaller in size, and not so pale in colour, as that same species in Bengal, while those from Timor are still more diminutive, and of darker hue. The beautiful *Coluber melanurus* inhabits Java, Sumatra, and the Celebes; but the individuals from the last-named locality have the nape of the neck constantly adorned by an angular black mark. *Herpetodryas oxycephalus* is of a beautiful grass-green colour in Java; but this pure tint becomes embrowned in Borneo, and in Celebes appears almost black upon the dorsal region. *Dendrophis picta* inhabits almost all the intertropical countries of the Old World, from Senegal to New Guinea, but varies considerably at distant points of such a vast and surprising distribution. *Dryophis nasuta* of Bengal and the Mariannas has in Java the abdomen rayed with yellow. *Dryophis prasina*, common in the isles of Sunda, exhibits a local variety in the Celebes; and *Tropidonotus quincunciatus*, a species widely spread through India, has in Java the spots confluent, so that the dorsal portion seems rayed with black. *Trop. chrysargos* of Sumatra bears a different aspect from that species in the Celebes, while both vary from the individuals found in Java. *Homalopsis Schneideri*, which is spread from India to New Guinea, exhibits several varieties in different regions. The great *Python bivittatus* occurs in China, the isles of Sunda, both the Indian peninsulas, and Ceylon, and is, moreover, distributed across Africa as far as Senegambia. In this vast extent of territory it exhibits some considerable variations, which, when the extreme differences merely are regarded, and the intermediate links kept out of view, have caused it to be described, in its different aspects, as distinct species, all however referable, in Mr Schlegel's opinion, to one and the same. *Elaps furcatus* and *bivirgatus* exhibit a different distribution of colours in Sumatra from what they do in Java; but it may be stated as a general fact, that almost all the known serpents of the former island have been found also in the latter. Indeed a considerable number of these insular Ophidians occur likewise both in Hindustan and Bengal.

It is a singular circumstance, that the two most remarkable species of the genus *Trigonocephalus* (*Trig. puniceus* and *rhodostoma*) have hitherto been observed only in Java; while *Trig. viridis*, so common in India, Bengal, Sumatra, and Timor, does not occur in the first-named island. The genus *Bungarus*, on the other hand, which inhabits Ceylon, Hindustan, and Bengal, does not occur in any other of the great eastern islands, except Java. In the Celebes we find many peculiar forms of animal life, combined with others well known elsewhere. Among the serpents we find there a beautiful species of *Herpetodryas* (*Herp. dipsas*), and *Dipsas irregularis*, which also occurs in Amboyna. Several species are absolutely the same as those of Java and Sumatra, although a few form permanent local varieties, which exhibit some slight disparities of colour. Such are *Tortrix rufa*, *Coluber melanurus*, *Herpetodryas oxycephalus*, *Dryophis prasina*, *Dipsas dendrophilus*, and *Tropidonotus chrysargus*. . Of the Moluccas our knowledge is extremely slight, being confined chiefly to the island of Amboyna. We there find three or four serpents, likewise known as Javanese species; but it does not appear that the isles of Sunda produce *Lycodon modestus*, *Boa carinata*, *Dendrophis rhodopleuron*, or *Python amethystinus*. Timor is in some measure intermediate in its productions between Java and the Moluccas. Its *Python* is perhaps different from that of Amboyna, and it produces a singular *Homalopsis* (*H. leucobalia*). *Lycodon hebe* is there of a deeper tint than in Java; and *Coluber radiatus* is represented in Timor by *Col. subradiatus*,—a species analogous, but not the same. New Guinea and the adjacent islands produce several new species. We know little of the reptiles of the Philippines, though a few have been collected in the environs of Manilla, in the island of Luçon; and these clearly establish the curious fact, that the species of that island bear a strong analogy to those of Ceylon,—not a few being identical. The *Naja* of the Philippines belongs to the ordinary variety of *N. tripudians*, as it occurs in India, and which always differs in some measure from the same species from the isles of Sunda.

The vast insular continent of New Holland is as yet but slightly known, most of its ascertained productions having been sent only from a few limited localities; but the anomalous and extraordinary character of its productions may even now be fairly inferred. The snakes seem peculiar, and almost all belong to the venomous division. No water species have as yet been seen there. It has already been observed, that the innumerable islands of the great Pacific Ocean are believed to be unproductive of serpents. The Mariannas, however, form an exception to this general rule, and Dampier mentions green serpents as inhabitants of the Gallipagos.

A few brief notices of the serpents of the New World may terminate the geographical department of our subject. On comparing the species of the two great continents of America with each other, we observe some interesting parallels. The rattle-snake, *Crotalus horridus*, so common over a large extent of South America, is represented in the northern territories by *Crot. durissus*, as is *Coronella venustissima* by *Cor. coccinea*. This kind of comparison, however, applies but to a few species, for the majority of kinds produced by one of the continents differ from those of the other. Thus, the genera *Tortrix*, *Dipsas*, *Dendrophis*, *Boa*, have as yet been found only in South America, or as far north as the Antilles, while *Tropidonotus*, on the contrary, is not found in the southern continent, though frequent in the northern, from which it likewise extends to parts of the West Indies. A small number, however, of southern species are found also in North America, such as *Calamaria melanocephala*, *Lycodon clelia*, *Coronella cobella*, *Herpetodryas cursor*, *Dryophis Catesbyi*, *Elaps corallinus*, *Homalopsis carinicauda*; while in like manner *Heterodon platyrhinus*, and *Herpetodryas æstivus*, which may be regarded rather as northern species, have been ascertained to inhabit Brazil. The following species of North American reptiles also inhabit the Antilles; *Calamaria striatula*, *Coronella coccinea*, *Heterodon platyrhinus*, *Coluber constrictor*, *Herpetodryas æstivus* and *cursor*, *Tropidonotus bipunctatus*, *fasciatus*, and *saurita*. Those next named also occur in the Antilles, although their proper country is South America; *Calamaria melanocephala*, *Coronella reginæ*, *Lycodon clelia*, *Dendrophys liocercus*, *Dryophis Catesbyi* and *aurata*, *Dipsas annulata*, *Homalopsis angulata*, *Boa constrictor* and *cenchria*, and *Elaps corallinus*. The species peculiar to these West Indian islands are very few in number, the most characteristic being *Psammophis Antillensis*, *Trigonocephalus lanceolatus*, *Dendrophis Catesbyi*, and *Boa melanura*. On comparing the snakes of Guiana with those of Brazil, we find many species common to both countries, several, however, forming local varieties more or less distinct, as in the cases of *Herpetodryas lineatus* and *Olfersii*, *Coluber poëcilostoma*, &c. Certain species are peculiar to one or other of the countries above named,—for example, *Calamaria badia*, *Xenodon typhlus*, *Coluber corais*, *Herpetodryas Boddaertii*, *Dendrophis aurata*, *Dryophis Catesbyi* and *argentea*, *Homalopsis plicatilis*, *Elaps lemniscatus* and *Surinamensis*, &c. have never been seen except in Guiana; while *Calamaria Blumii*, *Coronella Merremii*, *Xenodon Scholtii* and *rhinostoma*, *Lycodon formosus*, *Herpetodryas serra*, *Homalopsis carinicauda* and *Martii*, are found only in Brazil. Other species, again, appear as it were to represent each other in these parts of South America, so that we may place in parallel, *Coronella venustissima*, *Dipsas Mikani*, *Wegeli*, *leucocephala*, and *Nattereri*, and *Trigonocephalus Jararaca*, of Brazil, with *Coronella venusta*, *Dipsas nebulata*, *Catesbyi*, *macrorhina*, *punctatissima*, and *Trigonocephalus atrox* of Guiana. The other parts of South America are too little known to admit of any detailed comparison; but it

Ophidian Reptiles.

may be observed, that of the species discovered in Chili, several are entirely new, and distinct from such as exist on this side the Cordilleras.[1]

Notwithstanding the interest of the subject, we must now bring our general observations to a close, and proceed with a brief systematic sketch of the principal genera and species, referring the reader to M. Schlegel's work (and to those of the other Erpetologists here quoted) for more minute details. In conformity with the views of the author just named, we preserve the ancient subdivision of venomous and non-venomous kinds. The constant character of the former consists in being provided with a gland of a cellular structure, which secretes a very deleterious poison. Maxillary teeth, called fangs, of much greater length than the others, hollow interiorly, and furnished with openings at either extremity, for the entrance and exit of the poison, are the potent weapons with which these insidious reptiles inflict their fatal wounds. It is difficult, if not impossible, to assign to these serpents any certain character of external distinction, although there is something in their general aspect which points them out, even to the uninitiated, as dangerous neighbours. Their natural habits also offer this distinction, that the venomous kinds are almost always either terrestrial or marine, although *Trig. viridis* is slightly arboreal, and certain species of *Naja* occasionally occur in fresh water. But the colubriform venomous kinds so greatly resemble the innocent species, that professed naturalists have sometimes combined them with each other. Their most common characters consist in a thickish rounded muzzle, and a short, thick, conical tail. The marine serpents may be recognised by their flattened tails.

The constitution of the following families bears relation rather to the habits of life than the organic structure of the species they respectively contain.

FIRST PRIMARY DIVISION. NON-VENOMOUS SERPENTS.

Family I.—Burrowing Serpents.

Genus Tortrix. Body cylindrical, of nearly equal dimensions throughout; head small, obtuse, and covered by imperfectly developed plates; eyes small; nostrils narrow; gape not widely cleft; teeth short and conical; tail short. Plate CCCCXLIV. fig. 6.

The species of this genus (which in M. Schlegel's work includes also *Eryx* and *Xenopeltis* of other authors) inhabit the warmer countries of both the Old and New World, preferring dry and sandy districts, in which they form narrow excavations. *T. eryx* occurs over a vast extent of territory, from Egypt to Hindustan, and is met with in the southern parts of Europe. The ground colour of the dorsal region is a beautiful red with numerous confluent spots, and bands of blackish brown; the under parts are yellow, the whole covered by small scales. The muzzle is obliquely truncated at the end. Length about two and a half feet. Abdominal plates 195, caudal twenty. Six other species are known, of which *T. scytale* is American, and, of all undoubtedly Ophidian reptiles, makes the nearest approach to those ambiguous genera *Typhlops* and *Amphisbæna*.[2]

Family II.—Worm-like Serpents.

Genus Calamaria. Body small and cylindrical, terminated by a short conical tail. Head uniform with the body. Plates in the muzzle few in number.

The majority of the genus have the lower surface of a fine vermilion hue, a colour frequent among reptiles which inhabit low and moist abodes. They seldom exceed a foot in length, and are found in both the Americas, in Africa, Southern Asia, New Holland, and the Indian Archipelago. There are eighteen described species, of which one of the most curious is *Cal. lumbricoidea* of Boié.[3] Its body, though sometimes several feet long, does not exceed the thickness of a swan's quill. The colour is blackish-blue above, bluish below, with blackish spots, and a yellow ray along the sides. The scales are smooth, square, and disposed in thirteen rows. Abdominal plates from 190 to 217, caudal from sixteen to twenty-three.

Non-ven mous Serpent

Family III.—Terrestrial Serpents.

Genus Coronella. Body somewhat pentagonal, thickening towards the centre. Head distinguishable from the neck, sometimes very broad at the base, depressed, the muzzle short, obtuse, and slightly truncated. Scales smooth, and disposed in from seventeen to nineteen longitudinal rows. Abdominal and caudal plates about 180 + 40.

The species of this genus are very alert in their movements, and defend themselves, when attacked, with great energy and perseverance. They are dispersed over almost all parts of the world (preferring plains and humid places), but have not as yet been observed in Japan or New Holland, and are rather rare in Asia. Specimens from South America are very frequent in collections. *Cor. lævis* is a well-known European species, which occurs in France, Germany, Switzerland, Italy, and, from Sparmann's description, appears to be among the number of the few Ophidians which inhabit Sweden.[4] It is of a shining bay colour, ornamented by irregular black marks, which form a peculiar design upon the head. The under surface is yellowish, marked with square black spots. There are twenty-one rows of scales, and the plates are 175 + 55. This species is viviparous, that is, the young are hatched within the body of the mother. When attacked, it attempts to escape with great celerity, and when foiled in that intention, it fights with energy, bites furiously, and will scarcely allow itself to be taken alive. It cannot be lifted by the end of the tail (at least with impunity), as many serpents may, as it possesses the power of bending its body upwards, and wounding the hand of its captor. However, its bite, though disagreeable, is in no way dangerous. It is an excellent swimmer, but does not enter the water willingly. It is very fond of mice. About thirteen other species are known to naturalists.

Genus Xenodon. General form heavy, head broad, muzzle short and truncated, body thick, abdomen flattened. Upper jaws provided posteriorly with a solid, elongated, compressed tooth. Scales smooth, and dispersed in rather oblique ranges, especially on the neck, which is capable of expansion. Plates of the head short and broad.

Of this genus the species are few in number, and of these the individuals are by no means abundant. They are of large size, sometimes measuring from three to four feet in length, and, being thick in proportion, present a somewhat formidable aspect. They are usually characterized by a grayish-blue tint, and occur chiefly in Java and intertropical America. None have been as yet found in Africa or New Holland, but *Xen. Michahelles* inhabits the south of France and Spain.[5] This species is distinguished by its short conical head, terminated by a prominent rostral plate. It has twenty-seven rows of scales, and 216 + 60 plates.

Genus Heterodon. Head not very distinguishable from the general form, which is slightly pentagonal, and almost of equal thickness throughout. Abdomen somewhat angular, and narrower than in Xenodon. Tail very short, and furnished beneath with divided plates. Rostral plate always prominent, sometimes prolonged into a small upturned trunk.

[5] Figured by Wagler under the title of *Rhinechis Agassizii. Icones*, pl. 25.

All the species are natives of the New World. The prevailing colour is red, ringed or spotted by a deeper hue. Their manners are unknown, but it is presumed that they inhabit a dry and sandy soil. We shall here name only the harlequin snake of America (*Het. coccineus*), which inhabits Louisiana and the southern states.[1] The ground colour is a bright yellow, tending more or less to brown upon the back, which is adorned with above twenty broad round or oval spots, of a purplish-red colour, bordered with black. Its brilliant tints are effaced soon after death. "This beautiful snake," says M. Audubon, alluding, we believe, to our present species, "is rather rare in the United States, where I have observed it only in the south. It glides through the grass with ease, and ascends to the tops of bushes, and among the branches of fallen trees, to bask in the sun. Children are fond of catching it on account of its beauty. It feeds principally on insects, such as flies, and small Coleoptera."[2] This seems the species described by Herrera in his History of the West Indies, as inhabiting Mexico and the Floridas, where it is known by the name of *Madres de Hormigas*, on account of its frequenting the society of ants.

Genus Lycodon. Form usually thin, sometimes extremely slender. Anterior maxillary teeth longer than the others. Vertical and anterior frontal plates small and shortened, the occipitals rather long.

The species inhabit both the Old and New World. The prevailing tint is of an earthy hue, passing more or less into brownish or ochry-yellow, the majority of species being ornamented by a collar of a clearer colour. Several kinds are ringed with black, white, and red. The abdominal plates usually amount to 200, the caudal vary from fifty to a hundred. We know little of the habits of these reptiles, of which above a dozen species have been collected in different parts of the intertropical world.

Genus Coluber. This genus, as originally established by Linnæus, contained all the Ophidian reptiles with subdivided caudal plates. The venomous kinds were afterwards removed, and the genus itself partitioned into several groups; but even then the genus Coluber properly so called continued to contain a vast amount of species. MM. Boie and Schlegel restricted it still farther; and although it is difficult to apply the distinctive notes of these writers, the genus is natural in itself, when we seek to recognise it rather by the general bearing and physiognomy of the species, than by means of isolated characters.

It contains all those innocuous serpents of considerable size, which hold, as it were, by the form and proportion of their particular parts, a central position among the other Ophidians. Their bodies, less contracted than those of the fresh-water kinds, are yet by no means so slender as those of the arboreal species. Their head is not so lengthened as that of the latter, but is less broad than that of the aquatic sorts. The tail, modified in accordance with the nature of the species, varies in its form, as these resemble or recede from the conterminous groups in their mode of life. It is thus that certain species of the genus Coluber are closely connected with *Tropidonotus*, or even *Homalopsis*, while others are linked with *Herpetodryas*, *Psammophis*, *Coronella*, or *Xenodon*. The muzzle is usually broad, thick, rounded, rather short, the nostrils lateral, open, and oblong. The head is always laterally angular, from whence results the lateral position of the eyes, of which the pupil is orbicular in form. The body varies in proportional thickness in the different species, but is usually compressed, and slightly pentagonal. The abdomen is generally broad, convex, rarely angular, and is covered by numerous plates, more closely set together than in other serpents, and sometimes amounting to nearly 300. The tail is almost always cylindrical and pointed, generally of medium length, rarely slender and elongated, occasionally short and conic, its inferior portion furnished with divided plates.

Non-venomous Serpents.

Almost all the countries of the earth, of which the nature of the soil and climate is not altogether opposed to the existence of the Ophidian order, are inhabited by the genus Coluber. Only a single species, however, has been found in Southern Africa, and not one has yet occurred in New Holland. Their habits are what may be termed terrestrial, that is, they rarely enter water of their own accord, although several climb among shrubs and bushes with some celerity in search of prey. Several kinds occur in Europe, and those from intertropical countries measure in some instances from seven to eight feet. They are rarely adorned with brilliant colours, brown being the prevailing hue. Of some the markings are uniform, while others are spotted or longitudinally rayed. Of the European species, one of the best known and most extensively distributed is *Col. Æsculapii*, which sometimes attains to the length of from four to five feet. The colour of the upper parts is olive-brown, beneath yellowish, or marbled with gray, with a paler collar. Abdominal plates 228, caudal seventy-nine.[3] We have notes on the history of this species from MM. Host and Lenz. It is described as being extremely active in its movements, climbing trees with facility, but avoiding contact with water. It is oviparous, and feeds on lizards, frogs, and small birds, but takes no nourishment in captivity. When attacked, it defends itself with great determination; but when captured, becomes tame in a few days. In the museum of Vienna, several specimens of this Æsculapian snake are preserved alive; and their manners are so gentle that children make playthings of them, and handle them for hours at pleasure.

The ancient Greeks adored the god of medicine in various places under diverse forms, but frequently in the guise of a serpent, as an emblem of sagacity, and an animal endowed with so many sanatory qualities, that several Hellenic peoples regarded the creature itself as the very Deity. It was especially so with the inhabitants of Epidaurus (a flourishing city of Peloponnesus), who in a sacred grove, the favourite abode of serpents, erected a magnificent temple in honour of these by us abhorred reptiles. The Roman people, when terrified by a great pestilence, which ravaged the capital (in their year 461), sent an embassy to Epidaurus in search of this imaginary god, whom they might have found in sufficient abundance near at hand. They entertained these slimy deities in the island formed by the Tiber, and where we may still see their figure sculptured in marble in the gardens of St Bartholomew.[4] Chandler tells us, in his Travels, that the environs of Epidaurus still abound in harmless serpents.

The only other species we shall here notice is *Coluber quator-radiatus*, remarkable as being the largest of the Ophidian reptiles of Europe. According to Metaxa (in his *Monograph* of the Serpents of the Environs of Rome), it sometimes attains the length of seven feet. It occurs in Italy, the south of France and Spain, Dalmatia, Hungary, &c. Its prevailing colour is an ochry-yellow passing into brown, and somewhat deeper on the under surface. Two lines of darker brown run along the flanks, and a blackish line passes from the eye to the corner of the mouth. This species, in spite of its great size and formidable aspect, is

Non venomous Serpents.

extremely gentle in its manners, and does not attempt to bite even when seized in its native haunts. It is very common in the fields near Tivoli, but is usually found on hillsides. There is a passage in Pliny[1] which relates that the Boas of Italy sometimes attain to so great a size that the entire body of an infant was found in the interior of one slain during the reign of the Emperor Claudius. The species just noticed is certainly the largest of all the Roman serpents, but its natural attributes in no way favour the reception of this preposterous story.[2] The largest species of the genus is *Coluber corais* of Surinam. There are twenty-seven different kinds described by M. Schlegel.

Genus HERPETODRYAS. This genus was established by the late M. Boié for the reception of certain species of Coluber (*Col. carinatus*, &c.), which combine the aspect and physiognomy of the preceding genus (to which they are closely allied) with the lengthened form and much of the habits of the arboreal serpents. Their colours are usually of a uniform greenish hue, sometimes passing into brown, or occasionally longitudinally rayed. The tail is generally long and slender, a character which, combined with the narrow and very angular abdomen, announces their arboreal disposition. Their manners are wild and distrustful, and they inhabit the warmer regions of both the Old and New World, with the exceptions, so far as yet known, of Africa and New Holland. We shall here name only *Herp. carinatus*, a Brazilian species, also common in Surinam. It is remarkable for having two central rows of dorsal scales, so that the total number of rows forms an *equal* number, a character unique in the Ophidian order. It varies greatly in its external markings.[3]

Genus PSAMMOPHIS. This little group may also be regarded as a dismemberment from Coluber, and brings us into still closer contact with the genuine tree-serpents. They offer an anomaly in their dentition, in as far as their posterior teeth, and those of the centre, are usually longer than the others, and furrowed. The head is elongated, the vertical plate very narrow. Some have the body thin and long drawn out, while others are more compact like Coluber. The species occur in India, Africa, and America; and *Psam. lacertina* is an European example well known in Dalmatia.[4] They all prefer sandy soils, and prey chiefly upon Saurian reptiles. Green and brown are the prevailing colours, although several are longitudinally rayed, or have the head adorned by linear figures.

Family IV.—Arboreal or Tree-Serpents.

The members of this family are characteristic of the great forests of the tropical countries of Asia and America. They are rare in Africa, still more so in New Holland, and Europe produces only a few anomalous species. Their form is in general extremely elongated, they pass the greater portion of their time in trees and bushes, and prey both on birds and lizards.

Genus DENDROPHIS. Body compressed; abdomen (and sometimes the tail) angular, and furnished with very broad plates; scales narrow and elongated. Tail very slender. Head lengthened. Eye large, the pupil orbicular. See Plate CCCCXLIII. fig. 5.

These reptiles inhabit both the western and eastern world, but are rare in New Holland, and unknown in Europe. They climb trees with great facility, and are extremely quick in their general movements. They are frequently adorned by lively colours. Nearly a dozen species are known to naturalists.

Genus DRYOPHIS. Muzzle slender and projecting. General form greatly elongated, the body compressed, the abdomen convex. Eye of moderate size.

The species of this genus are among the most remarkable of the innocuous serpents, their shape being so extraordinarily lengthened out, that many measure nearly five feet in length, and are yet no thicker than the little finger. Hence their Anglo-American name of coach-whip snakes, of one of which, first described by Catesby, it was absurdly believed by the Indians, "that it will by a jerk of its tail separate a man in two parts."[5] The tail, of extreme slenderness, always measures half the length of the whole body; and the muzzle is often drawn out in the form of a pointed proboscis. These reptiles inhabit the torrid zone, or the countries near the tropics, in Asia and the two Americas. Although unknown in the continent of Africa, a species (*D. langaha*) occurs in Madagascar. The genus admits of a geographical division,—those of the ancient continent being characterized by grooved maxillary teeth, and the pupil of the eye elongated horizontally, while such as inhabit America have the teeth less developed, and the pupil orbicular. We may briefly notice *Dryophis nasuta* (the *Passeriki* of Russel),[6] a remarkable species, of a beautiful grass-green colour above, the lower surface paler, and marbled with red. A white or yellow ray extends from behind the eye to the commissure of the lips, and another very distinct one passes along each side of the abdomen and tail. The muzzle is very sharp, and is terminated by a moveable fleshy appendage (See Plate CCCCXLIII. figs. 7 and 9.) This kind occurs over a great extent of India and the great eastern islands, and is frequent in the environs of Vizagapatam. It lives in trees, and its manners are described as being even ferocious. Its bite, however, is attended by no other bad consequences than the pain of the wound; but the common people deem it dangerous, as directing its attacks chiefly at the eyes of the passers by. There is an Indian whip-snake (probably not of this genus) common in the Concan, where it is described as concealing itself among the foliage of trees, from which it darts at cattle grazing below, generally also aiming at the eye. A bull which was thus wounded at Dazagon tore up the ground with extreme fury, and died in half an hour, foaming at the mouth. This habit of the reptile is truly singular,—for it seems to proceed neither from resentment nor from fear, nor yet from the impulse of appetite, but seems, "more than any other known fact in natural history, to partake of that frightful and mysterious principle of evil, which tempts our own species so often to tyrannize for mere wantonness of power."[7]

The species already named as a native of Madagascar, *Dryophis langaha*, Schlegel, partakes of those anomalous attributes which characterize so many animal products of that extraordinary island. It measures between two and three feet in length, and is of a beautiful reddish-brown colour above, the under surface being of a deep though lively yellow, spotted with brown, especially beneath the tail; but its most peculiar character is seen in the muzzle, which is prolonged into a fleshy appendage of half an inch in length, covered with small scales, and of variable form, being in some cases sharp-pointed, in others compressed and enlarged, or leaf-shaped. This curious reptile seems to have been first (we believe inaccurately) described by M. Bruguières,[8] and has since been banded about through various genera.[9] It is classed by M. Schlegel (we presume after due examination),[10] among the innocuous, that is, the non-venomous kinds,—although the natives of Madagascar veno-ous pents.

Non-venomous Serpents.

are said to hold it in great dread, from the belief of its being a highly poisonous species.[1]

Genus Dipsas. Head thick, broad, obtuse; the body vigorous, but much compressed. Pupil of the eye usually vertical. Plate CCCCXLIV. fig. 7.

This genus comprises all those tree-serpents which, resembling the Colubers (and so far differing from the two preceding genera) in the bulkier proportion of their parts, are distinguished by their compressed bodies and more slender tails. Both the size and colours differ greatly according to the species, some of which do not measure more than fourteen inches, while others extend to five or six feet. South America and the East Indies are their characteristic countries, although a somewhat anomalous species is found in Egypt and Dalmatia. The genuine Dipsas dwell habitually in trees, concealing themselves amid dense foliage, from whence they dart upon their unsuspecting prey. The largest species known to naturalists is *Dip. dendrophila*, a Javanese reptile, which sometimes measures seven feet in length. The ground-colour is a beautiful lustrous black, with steel-blue reflections, paler on the under surface; and the body is encircled by from forty-five to fifty transverse narrow bands of a fine golden yellow.[2] *Dip. fallax* is, we presume, the sole European species,—if the reptile so named really pertains to our present genus.[3] Its habits offer great disparity, at least M. Cantraine found it in Dalmatia in the month of December, creeping slowly among the ruins of an ancient castle. It had previously been found in the Levant by Olivier, and was more recently observed in the Morea by M. Bory St Vincent. Fleischman informs us that it lives under stones, stirs abroad only in the early morning and towards evening, avoids water, and feeds on insects, lizards, and mice. About twenty-five species of this genus are described by M. Schlegel.

Family V.—Fresh-water Serpents.

The members of this group are more or less allied to Coluber in their organization. They inhabit the water, or at least frequently enter into that element, and prefer the banks of rivers and the shores of lakes to situations more remote from moisture. It does not follow that all snakes endowed with analogous instincts and manners belong to this group, because the majority of the Boas, and almost all the Colubers, nearly correspond in their habits of life, and are yet very dissimilar in their structure. In this family there are combined those serpents which, having many mutual relations in their form and physiognomy, constitute a very natural assemblage, though by no means distantly separated from all other subdivisions. It is composed of two genera, of which the first exhibits, with few exceptions, nothing remarkable in its organization,—while the second is characterized by several singular features.

Genus Tropidonotus. Head broad, body rather bulky, abdomen broad and convex, tail short.

The majority of this genus inhabit Asia, especially the Indian Archipelago. Southern Africa produces only a single species; Europe two, which occur on both sides of the Mediterranean basin. The same restricted number is found in Japan, and several are native to North America. None is known to inhabit either South America or New Holland. Certain species are widely distributed, while others are confined within narrow limits. They usually occur along the shady, wooded banks of lakes and rivers, where they prey on frogs and fishes. They swim with great dexterity, and are capable of continuing for a length of time beneath the surface. Although they can both creep and climb with considerable swiftness, they usually prefer to escape from threatened danger by plunging into water. Many species never remove from the close vicinity of that element; others inhabit plains subject to inundation; and a few are found to dwell in moist umbrageous forests, even on the sides and towards the summits of high mountains. Certain species are gregarious; while some are solitary, dwelling in the deserted holes of small quadrupeds. Such as inhabit temperate climates fall into a lethargic state in winter. The whole are oviparous; but the eggs of many, even when newly laid, contain young in a state of considerable advancement.

The first species we shall notice is *Tropidonotus natrix* (*Coluber natrix*, Linn., *Natrix torquata*, Ray), the best-known and most generally-diffused of European serpents, and one of the few which inhabit the cold and cloudy clime of Britain. We have exhibited its osteology on Plate CCCCXLIV. fig. 2. It is subject to great variation of colour, but the prevailing tint is a pale ashy-blue tinged with green, and relieved by a series of black spots or bands. The under surface is dusky blue, with mottlings of yellowish white. The collar is white or yellow, bordered posteriorly by deep black; and the plates of the head are extremely regular in their form. The length ranges from two and a half to four, or occasionally five feet. The female is always the larger. This reptile has been studied and described by a host of European writers. It is not characterized by any wildness or ferocity, is easily tamed, and rarely bites even when seized. "Il m'est cependant arrivé," says M. Schlegel, "qu'étant encore très-jeune, et m'étant approché du bord d'un bois, où une société nombreuse de ces serpens s'était établie pour faire leur ponte, un Tropidonote d'une taille énorme m'attaqua avec fureur, tandis que plusieurs autres s'échappaient dans les trous dont la terre était percée."[4] The ringed snake, as our present species is generally named, prefers to take possession of the subterranean dwelling of a mouse or mole to commencing an excavation for itself. Being fond of warmth and shelter, it often approaches human habitations, and readily lays its eggs in dunghills. Yet it is often met with in the remotest wilds, or in thick umbrageous forests, and sometimes at a height of several thousand feet above the level of the sea. But on the whole it prefers the vicinity of tranquil waters, where it dives frequently in search of fishes, as well as of frogs and other batrachian reptiles. Although it possesses the power of remaining under water for nearly half an hour, it is not organized for a continued abode in that element; and when frequently forced from shore, its swimming powers become exhausted, and it is "found drowned." It is extremely voracious, and will swallow a great number of frogs at a meal. It hybernates, in cold and temperate countries, from the month of October or November, seeking profounder excavations, where frost can scarcely enter. It leaves its retreat in March or April, according to the region it inhabits, and casts its skin once a month till the end of August. In that month also it lays its eggs, to the number of two dozen or more. As the species pairs in April, it follows that these eggs take five months to be developed in the oviducts, though they are hatched in about three weeks after deposition. Their form is oval, and they measure about an inch and three lines in length. The young, when first visible, measure from six to eight inches. This species abounds over all France and Germany. It does not inhabit the maritime parts of Holland, but is common in Guelderland and the province of Drenthe. It is well known in Italy, Sicily, and Sardinia, as well as in Denmark, Sweden, and Norway, and extends over a great portion of temperate

Asia, as far as Lake Baikal. It is a common species in England, where it occurs in woods and hedges, as well as in marshes. Mr Jenyns informs us, that it is particularly abundant in the fens of Cambridgeshire, where it sometimes attains a great size.[1] We shall merely add, that it is eaten in several continental countries. *Col. viperinus*, another European species, pertains to this genus; as do also a considerable amount of exotic kinds, which we cannot here so much as name.

Genus Homalopsis. Body bulky, head very thick, muzzle short and rounded; eyes and nostrils small, and opening upwards; form usually cylindrical, sometimes slightly compressed; abdomen broad and convex; tail short, conical, robust.

This genus inhabits the great fresh waters of the intertropical countries both of Asia and America, although it seems less extended than the preceding, being seldom seen beyond the tropics. A Bengal species occurs also in Java, and a few are found identically the same in both the Americas. The majority attain a considerable size; but though as thick as a man's arm, they rarely exceed the length of four feet. Their heavy inelegant forms, small insidious eyes, and large gaping mouths, confer upon them a peculiar and repelling physiognomy; yet they are quite innocuous, in spite of the malignity of their aspect, a proof that we should never judge from appearance. These are the most truly aquatic of all the fresh-water serpents, passing almost their entire lives submerged, and feeding chiefly on fish. They are endowed with great muscular strength and strong powers of locomotion in their favourite element. Their colours are usually dark and lugubrious,—a schistose gray, brown, olive, or a blackish hue prevailing over the upper surface; while a yellower tint, with large square spots, is frequent on the abdominal region. We are acquainted with few details regarding their habits of life; and the species are rare in collections, probably in consequence of their fish-like activity in the water rendering their capture difficult. They are distributed over a variety of genera by different naturalists; and M. Schlegel describes fourteen species, among which are included *Hom. herpeton* (*Erpeton tentaculatus*, Lac.[2]), a serpent remarkable for two fleshy appendages covered with scales, which extend from the termination of the muzzle. (See Plate CCCCXLIII. fig. 4.) The abdominal plates are scarcely broader than the other scales, and each is surmounted by a couple of ridges. Its native country is unknown.

Family VI.—Boas.

This family, according to M. Schlegel's views, comprehends the greater number of those species which modern naturalists have comprised under the genera *Boa*, *Python*, and *Acrochordus*. It is one of the most natural of the entire order, and has been too often erroneously separated, merely on the consideration of a few unimportant characters. We here find species, some of them the largest of the Ophidian race, distinguished by a prehensile tail, and a body possessing the power of twisting itself around other bodies with great force and facility. The surface is encompassed by numerous small scales, which advance upon the head and encroach on the abdomen, so that the former part never exhibits the regularly-formed plates of the Colubers, while those of the latter are unusually narrow. The vertical position of the nostrils and small-sized eyes announce a combination of aquatic with terrestrial habits of life. The first genus, that of *Boa* properly so called, is characterized by simple plates beneath the tail; the second, *Python*, peculiar to the ancient world, exhibits the subcaudal plates divided, a supernumerary bone on the upper margin of the orbits, and intermaxillary teeth; the third, *Acrochordus*, is destitute of anal hooks, and has the surface entirely covered over by small granular unimbricated scales. All these generic groups have many characters in common, both in habits and organization, and we shall here point out a few of their generalities.

The term *Boa*, according to Pliny,[3] is derived from *Bos*, because the young of these reptiles are wont to nourish themselves on cow's milk.[4] We are farther informed by that credulous author, of the great Boa slain in the Vatican, within the abdomen of which was found an entire infant. Linnæus applied the name to all serpents provided with simple sub-caudal plates. It is obvious that his genus, founded on a character of such slight importance, while it excludes the Pythons, necessarily brings together several heterogeneous groups. The defect in the modern arrangement of these reptiles arises chiefly from the practice of viewing a single and often subordinate character, and ruling, as it were, the forms of nature in simple accordance with its absence or existence. We thus find the Pythons almost always separated from the Boas, and placed in the genus Coluber, while the Acrochordi, estranged from both, comprise two distinct genera, sometimes placed among venomous serpents, sometimes classed with the innocuous kinds. " Nos temps," says M. Schlegel, " fertiles en invasions de toute sorte, ont vu démembrer la famille des Boas en autant de divisions génériques que l'on en compte d'espèces, qui elles-mêmes sont multipliées sans le moindre fondement de verité. Il n'est pas rare de voir la même espèce distribuée en deux ou trois genres différens, et ces genres placés au hazard parmi d'autres Couleuvres ou parmi les vipères." The opportunities enjoyed by the author just named, of studying the various species, has led him to the belief that these are much less numerous than generally supposed. He thinks that the majority of such as exist in nature are now in some measure known, and that they do not amount to more than fifteen, including *Acrochordus*. Various anomalies exist among the species when compared among each other. Some are spread over a vast tract of territory, while others are confined within narrow limits. They are all, however, inhabitants of countries either situate beneath the equator or near the tropics. They occur in both the Old and New World, but none is found in Europe, North America, or Japan. The South American species are frequent in collections; those of the (so-called) more ancient countries of the earth are rather rare. Some are oviparous, others produce their young alive. The Boas usually attain, in truth, to an enormous size, although their actual dimensions have been greatly exaggerated. Thus at the very name of *Boa constrictor* the imagination is filled " with folds voluminous and vast," although the species really so called scarcely ever exceeds ten or twelve feet in length. The largest Ophidian reptiles in the world are *Boa murina* and *Python Schneideri* and *bivittatus*; but it may be greatly doubted whether the first named, which is the most gigantic of all, ever exceeds twenty-five feet in these degenerate days, and we have no sufficient

[4] " Quant aux véritable serpens, il n'en est pas qui mâchent réellement, de même qu'il est evident qu'aucun ne peut sucer ou opérer le vide dans la bouche, et que, par consequent, c'est un préjugé de croire que plusieurs de ces animaux, comme les Boas et les Couleuvres, puissent téter les vaches; outre l'absence des lévres charnues, le defaut de voile du palais et de l'épiglotte, qui rendraient la succion impossible, il est evident que les crochets acérés et recourbés en arrière, qui garnissent leurs mâchoires et leur palais, s'accrocheraient comme des hameçons aux tétines des mammifères et qu'ils ne pourraient s'en detacher." (*Erp. Gén.* i. 135.)

veno-
us
nts.

reason for supposing that it was ever any larger in former times.[1] The recitals of our travellers have been too often drawn, not from their own observation (by no means accurate at the best), but merely from the popular belief of ignorant and superstitious natives. The Pythons of the Old World seldom exceed from eighteen to twenty feet in length; and we can easily believe that one even of that extent being met by a benighted traveller in some lonesome forest glade, or murky meadow, might be afterwards described as something super-serpentine. Who in early life (how few at any period) ever caught a trout of two pounds or a pike of ten, without at least supposing that the one weighed four, the other fifteen? Yet who fears the innocuous finny race, and how greatly must doubt and dismay increase the seeming dimensions of a huge lugubrious reptile, weaving its way through some "wild wood, dingle or bushy dell," and dimly seen in sombre twilight hours, by snatches of only four or five yards at a time? The same exaggeration prevails regarding both the size of their natural prey, and its mode of capture. The lamented Boié, who made numerous observations on the Pythons of Asiatic countries, states that they particularly attack only the smaller kinds of quadrupeds, although individuals of unusual size sometimes swallow a young pig, or that species of deer called muntjac. But the larger mammiferous animals, and the human race more especially, need entertain no reasonable expectation of attack; and Prince Neuwied confirms this statement of the lamented naturalist of Kiel, so far as concerns the great species of the New World, which prey chiefly on birds and reptiles.

Boas are said to be by no means difficult to tame. M. Dieperink of Paramaribo informed M. Schlegel that he was in the practice of keeping by him several different kinds of live Boas, all of which lived in perfect harmony, both among themselves and with other domestic animals. Professor Reindwardt, however, was witness at Java to a spectacle which proved that these great serpents are not always as merciful as they are strong. A native of the island having brought to the Baron Van Der Capelle a huge Python, and being desirous to make it leave a pannier in which it was contained, the monster rose upon him suddenly, and inflicted a severe wound, at once laying open the fore-arm throughout its entire extent. It may be as well, then, upon the whole, not to allow the serpents of this family to sleep at large in the bed-chambers of any other family where there are small children.

The members of our present group seize their prey suddenly by ambuscade, usually lying in wait for it in the vicinity of water. They fix upon it with their teeth, and then, if of tolerable size or strength, entwine their folds around it, pressing out the breath of life, or even bruising the body, and breaking the bones in pieces. To aid this act of butchery, some of the species are said to keep their tails twisted around a tree, to which they drag their reluctant victim,—making use at the same time of the hard and gnarled trunk to give a still stronger stringency to their dreadful coils, while the faint-hearted prey

Clamores simul horrendos ad sidera tollit.

Non-venomous
Serpents.

When the animal attacked is of smaller size, it is merely *mouthed*, always head foremost, covered with saliva to hasten putrefaction and aid deglutition, and afterwards swallowed at leisure. These gigantic reptiles are endowed with great muscular force, which, however, they rarely exercise in a state of captivity. They seem extremely lethargic when imported into Europe; many of them, if not gentle in their manners, at least cannot be induced to bite by any provocation; their movements are very slow, they rarely eat, and the majority indeed die after a few months' confinement, without having tasted food.

The following curious, and we doubt not accurate, account of the swallowing powers of one of the great Asiatic serpents, has been recorded by Mr Macleod. He calls the species *Boa constrictor*, which, as it was captured in Bornea, it could scarcely be. It belonged, we presume, to the genus Python, and measured sixteen feet in length by about eighteen inches in circumference. We shall make no apology for the size of the ensuing extract, as it so clearly illustrates the peculiar manners and the mode of deglutition of these Boa-like serpents.

"The live stock for his use during the passage, consisting of six goats of the ordinary size, were sent with him on board, five being considered as a fair allowance for as many months. At an early period of the voyage we had an exhibition of his talent in the way of eating, which was publicly performed on the quarter-deck, upon which he was brought. The sliding door (of his cage) being opened, one of the goats was thrust in, and the door of the cage shut. The poor goat, as if instantly aware of all the horrors of its perilous situation, immediately began to utter the most piercing and distressing cries, butting instinctively at the same time with its head towards the serpent, in self-defence. The snake, which at first appeared scarcely to notice the poor animal, soon began to stir a little, and turning his head in the direction of the goat, he at length fixed a deadly and malignant eye on the trembling victim, whose agony and terror seemed to increase; for, previous to the snake seizing his prey, it shook in every limb, but still continuing its unavailing show of attack, by butting at the serpent, which now became sufficiently animated to prepare for the banquet. The first operation was that of darting out his forked tongue, and at the same time rearing a little his head; then suddenly seizing the goat by the fore leg with his mouth, and throwing it down, it was encircled in an instant in his horrid folds. So quick, indeed, and so instantaneous was the act, that it was impossible for the eye to follow the rapid convolution of his elongated body. It was not a regular *screw-like* turn that was formed, but resembling rather a knot, one part of the body overlaying the other, as if to add weight to the muscular pressure, the more effectually to crush his object. During this time he continued to grasp with his fangs, though it appeared an unnecessary precaution, that part of the animal which he had first seized. The poor goat, in the mean time, continued its feeble and *half-stifled* cries for some minutes, but they soon became more and more faint, and at last it expired. The snake, however, retained it for a considerable time in his grasp after it was apparently motionless. He

---

[1] Unable as we are either to confirm or contradict, from personal experience, the reported observations of travellers regarding the supposed dimensions of these huge reptiles, we are under the necessity of stating the different opinions which prevail upon the subject, however irreconcileable these may sometimes seem with each other. The following quotation rather favours the idea of their great size and unexampled voracity. "In the Dutch colonies of the East Indies, André Cleyer purchased of the hunters of the country an enormous serpent, in the body of which he found a deer of middle age, altogether entire, with its skin and limbs. In another individual of the same species, also examined by the traveller, a wild he-goat was found, with its horns; and a third had evidently swallowed a porcupine with its quills. He adds, that a pregnant woman also became the prey of a reptile of the same genus in the island of Amboyna; and that this kind is sometimes kept for the purpose of attacking the buffaloes in the kingdom of Aracan, on the frontiers of Bengal. We need hardly be astonished at this, when Prince Maurice of Nassau-Siegen, one of the governors of Brazil, in the seventeenth century, assures us that he himself was an eye-witness of stags, and other equally voluminous mammifera, and even of a Dutch woman" (usually a considerable mammifer), "being devoured in this manner, in that region of South America where he commanded." Griffith's *Animal Kingdom*, ix. 295.

Non-venomous Serpents.

then slowly and cautiously unfolded himself, till the goat fell dead from his monstrous embrace, when he began to prepare himself for swallowing it. Placing his mouth in front of the dead animal, he commenced by lubricating with his saliva that part of the goat; and then taking its muzzle into his mouth, which had, and indeed always has, the appearance of a raw, lacerated wound, he sucked it in as far as the horns would allow. These protuberances opposed some little difficulty, not so much from their extent, as from their points; however, they also in a very short time disappeared, that is to say, externally; but their progress was still to be traced very distinctly on the outside, threatening every moment to protrude through the skin. The victim had now descended as far as the shoulders; and it was an astonishing sight to observe the extraordinary action of the snake's muscles when stretched to such an unnatural extent,—an extent which must have utterly destroyed all muscular power in any animal that was not, like himself, endowed with very peculiar faculties of expansion and action at the same time. When his head and neck had no other appearance than that of a serpent's skin, stuffed almost to bursting, still the workings of the muscles were evident, and his power of suction, as it is erroneously called, unabated; it was, in fact, the effect of a contractile muscular power, assisted by two rows of strong, hooked teeth. With all this, he must be so formed as to be able to suspend, for a time, his respiration; for it is impossible to conceive that the process of breathing could be carried on while the mouth and throat were so completely stuffed and expanded by the body of the goat, and the lungs themselves (admitting the trachea to be ever so hard) compressed, as they must have been, by its passage downwards.

"The whole operation of completely gorging the goat occupied about two hours and twenty minutes; at the end of which time the tumefaction was confined to the middle part of the body, or stomach, the superior parts, which had been so much distended, having resumed their natural dimensions. He then coiled himself up again, and lay quietly in his usual torpid state for about three weeks or a month, when, his last meal appearing to be completely digested and dissolved, he was presented with another goat, which he killed and devoured with equal facility."[1]

As the vessel, which was sailing from Batavia to England, approached the Cape of Good Hope, this gigantic reptile began to droop, as was at first supposed, from the increasing cold. It refused to kill some fowls which were presented, and died before reaching St Helena. On dissection, the coats of the stomach were found to be "excoriated and pierced by worms!" Nothing of either goat remained except a single horn. During a prior captivity of some months at Whidah, in the kingdom of Dahomey, Mr Macleod had enjoyed opportunities of observing snakes "double the size of the one just described." These killed their prey in the same manner; but from their superior bulk were capable of swallowing much larger animals than either goats or sheep. Governor Abson, who had resided for nearly forty years at Fort William, a settlement of the African Company, used to describe some desperate struggles which had taken place between these great serpents and various wild beasts, as well as smaller cattle. A negro herdsman was once seized by the thigh, but the monster, in attempting to entwine itself around him, got entangled by a tree, and the man being armed with a knife, had presence of mind to inflict several severe gashes on the neck and throat, which enabled him to disengage himself from the dreadful coils which were closing fast around him. But he remained lame for life, in consequence of the wound and heavy pressure inflicted by the jaws.

Non-veno mous Serpen

The natural colours, which are various in this family, disappear speedily after death. Some are brown upon a yellowish ground, others exhibit a uniformly greenish hue, red prevails among certain species, while a few are nearly black. Almost all are more or less spotted; and it has been observed that, unlike the smaller tribes of serpents, these markings continue equally, or rather more distinct, as the individual increases in years. The body of the Boas is thickest at the middle, tapers towards either end, and is always considerably compressed. The abdomen is broad, and slightly convex or keeled. The tail is shaped like the body, but is more slender, not very conical, and usually terminates in a blunted point. It is always prehensile, that is, possesses the power of rolling inwards upon itself, or forming convolutions around other bodies. The scales in general are rather small, and as they encroach considerably on the under surface, it follows that the abdominal plates are narrower than usual. There are sometimes from sixty to seventy ranges of scales, and about two hundred and fifty abdominal plates. The number of these, however, is greater in the Boas of the ancient world than among the American species, which moreover differ in several other respects; while the genus *Acrochordus* is distinguished from all its congeners by the small granular scales which clothe the entire surface, and of which a double series prevails along the median line of the abdomen, forming a kind of projecting ridge or keel.

The head of the Boas is always distinguishable from the trunk, being thick, rather lengthened, conical, depressed, and terminated by a muzzle for the most part elongated, and truncated at the point. The eyes are placed at some distance from the nostrils, and are lateral in the terrestrial species, of which the head is flattened above, and more or less angular on the sides; but the more aquatic kinds have the eyes rather vertical. These organs are always small in our present family, and, excepting *Acrochordus*, have the pupil horizontally elongated. The nostrils are broad, closely approached to the end of the muzzle, and in some are placed upon its summit. They open upwards in the genus just named, and assume a tubular form. All the species are provided with palatine teeth, nearly as much developed as the maxillary ones; but there are no intermaxillary teeth except among the Pythons. The glands of the head are less developed in this family than among the majority of Ophidian reptiles.

Genus BOA. No intermaxillary teeth. Space between the orbits formed solely by the frontals properly so called. Subcaudal plates simple.[2] See Plate CCCCXLIII. figs. 8–11.

This restricted genus includes the largest of Ophidian reptiles, and although composed chiefly of South American snakes, it also contains three Asiatic species, which, though of much smaller size, cannot be regarded otherwise than as a geographical division.

Boa constrictor, Linn., is a middle-sized species, which rarely exceeds the length of ten or twelve feet.[3] It is of a reddish tint, elegantly marked by irregular reticulations of

---

[1] Macleod's *Voyage of the Alceste*, p. 290.

[2] This is the prevailing character of these parts, although we find in this, as in many other cases, a difficulty in seizing upon single determinate features of constant application. Thus we sometimes meet with several divided plates in the sub-caudal region of these so-called Boas.

[3] The true *B. constrictor* is often confounded with the more gigantic *B. murina*, and its dimensions have in consequence been greatly exaggerated. We doubt if any existing species ever attains to the alleged size of the so-called *B. constrictor*. Mr Swainson, however, who has travelled in South America, and is himself a zealous student of the facts of zoology, both as recorded in books and as existing in nature, states that the young individuals frequent in our menageries are mere pignies in comparison to the

-veno- ous pents.

brownish black, and other hues, and is subject to a great variety of aspect, so far as colour is concerned. It is, however, well characterized by the small smooth scales which cover both head and body, and of which there are sixty-seven rows. The head is heart-shaped, and the tail short. Abdominal plates 243, caudal fifty-eight. This species is native to the intertropical countries of South America, and not only have its size and voracity been greatly exaggerated, but many traits have been applied to it which truly belong only to the Pythons of the ancient continent. Thus the very name of *Devin*, bestowed upon it by Lacépède, is borrowed from what Bosman relates of the worship accorded by the negroes to certain African reptiles. It is met with in Surinam and Brazil, in woody districts, being sometimes seen suspended from the branch of a tree, sometimes concealed in the hollows of rocks, or beneath an ancient trunk. It is feared by no one, is often killed with a short walking-stick, and is commonly known by the name of *Jiboya*. It feeds on small and middle-sized mammalia, such as mice, rats, agoutis, pacas, and capybaras, as well as on various reptiles. A hunter, however, assured the Prince of Neuwied, that his dog on one occasion would have fallen a victim to a Boa of this species, had he not contrived to shoot it during the combat. The true constrictor does not enter the water. The Brazilians take it by means of gins, and employ its skin for making boots and saddle-cloths. They also use its fat. All engraved representations of this species, having been made from ill-prepared museum specimens, are worse than indifferent.[1]

The rat-eating Boa, *B. murina*, Linn. (*B. Anaconda*, Daud.[2] *B. aquatica*, Neuw.[3]), is the largest Ophidian reptile of America, and probably the most gigantic of known species. It is distinguished in Brazil by the title of *Cucuriuba*, and passes a great portion of its time in the water, either swimming about in various directions, or floating lazily with the current. It dives with great dexterity, can remain for a length of time beneath the surface, and is said to prey on fish as well as quadrupeds. It is tenacious of life, and is killed by the natives either with bow or musket in the water, or with sticks when met with on shore, where its movements are somewhat sluggish. Both its skin and fat are used for various purposes, and its flesh is eaten by the Botocudes. M. Fermin measured one which had attained the length of twenty-three and a half feet; and the Prince of Neuwied was assured by the natives that it is often much longer, although he himself never saw one above twenty feet. This species exhibits less varied markings than the preceding. The general hue of the upper parts is sooty brown, with two rows of orbicular blackish spots along the back. The under surface and sides are of an ochry yellow, the latter marked with a double row of irregular eye-shaped spots, which confound themselves with numerous squarer spots upon the belly. The nostrils are vertical, the eyes also directed upwards. The head is of an elongated form, with a rounded muzzle. Abdominal plates 250, caudal sixty-six.

Non-venomous Serpents.

The other species of this genus are *B. cenchria*, *canina* (Plate CCCCXLIII. figs. 8–11), *hortulana*, from South America; *B. Dussumieri*, from a small island near the Mauritius; *B. carinata*, from the Moluccas and New Guinea; *B. conica*, from Bengal; and *B. melanura*, from the island of Cuba.

Genus PYTHON. Several intermaxillary teeth. Upper portion of the orbit formed by a particular bone incased among the three frontals, and named super-orbital by Cuvier. Sub-caudal plates usually divided. Lips hollowed out in front. Plates of the head larger and more regular than in Boa. See Plate CCCCXLIII. figs. 1*b*, 1*c*, and 3, and Plate CCCCXLIV. fig. 5.

This genus was established by M. Daudin for the reception of the great serpents of the ancient world. Brown, black, and yellow, are their prevailing colours. Certain of the species equal (some say exceed) the Boas of America in size, for example the *Ular-sawa* (*Python bivittatus*, Khul,—*Col. Javanicus*, Shaw). This species is of a yellowish tint, relieved by a pattern of broad alternate brown spots. The top of the head is margined by two rays of the ground colour. The flanks are variously adorned by black and white, and the under surface is marked by deep square spots. There are sixty-three ranges of smooth small scales, 270 abdominal and seventy caudal plates. This great reptile is spread, according to M. Schlegel, over a vast extent of territory, being known to occur from the western coast of Africa, over the whole of intertropical Asia, as far east as China and the island of Java. It is said to attain the length of twenty-five feet, and individuals of twenty feet in length have been seen and described by trustworthy naturalists. A fine specimen lived for some time in Holland, and was observed to be slow in its movements, mild in its temper, and never inclined to bite even when provoked. It was kept in a large box enveloped in woollen cloths, where it lay in continued tranquillity, and suffered itself to be drawn out for frequent exhibition without manifesting any signs of anger or impatience. We suspect that the senses of this, and of other large tropical snakes, are so far benumbed by the change of climate in Europe as to produce stupefaction rather than tameness. The specimen in question was presented with food every eight days, which, however, it often refused for several successive times. It was most easily excited to eat by the sight of a live rabbit, into the head of which it would fix its teeth, and then, placing it within a fold of its body, deprived it almost instantly of life. After the commission of this murder, it was in no hurry to swallow its victim, but sometimes licked it for a while, occasionally taking two or three hours to effect the final deglutition. This is supposed to be the *Pedda-poda* of Dr Russel, called rock-snake by the Anglo-Indians.[4]

We do not happen to know to what extent this or any

---

adults, "which have been *often found* to exceed *forty feet* in length" (*Cabinet Cyclopædia*, vol. cxvi. p. 143). Yet he does not state this as a result of observation, or as connected with his own knowledge as well as belief. A single specimen of such gigantic reptile would be the wonder of Europe, and would make a fortune for its owner. A Dutch friend of Mr Waterton's killed a Boa (he does not say of what species) twenty-two feet long, with a pair of stag's horns in its mouth. It had swallowed the stag, but could not swallow the horns (at which we are not much surprised), and so had to wait in patience with that uncomfortable mouthful till its stomach had digested the body, "and then the horns would drop out." It was in this expectant plight that the Dutchman found it, as he was going in his canoe up the river, and sent a ball through its head (*Wanderings in South America*, third edit. p. 209). The large serpent *bagged* by Mr Waterton, after "a sharp fray in the den, the rotten sticks flying on all sides, and each party struggling for superiority," measured rather more than fourteen feet in length. It was of the kind called *Coulacanara*, a rare species, and so much thicker in proportion to its length than any other snake of the forest, that an individual of the extent just stated "is as thick as a common Boa of twenty-four." Its jaws are so extensile, that Mr Waterton, after skinning his specimen, could easily get his head into its mouth.

[1] See Scheuchzer, *Biblia Sacra*, pl. 746, fig. 1:—Lacép. *Quad. Ovip.* ii. pl. 16, fig. 1:—Daudin, *Reptiles*, v. pl. 92, fig. 1. There are various figures of our *B. constrictor* in Seba's *Thesaurus*, and from these Laurenti seems to have composed such species as *Constrictor formosissimus*, *Rex serpentum*, *diviniloquus*, and several others.

[2] *Reptiles*, v. 161, pl. 63.

[3] *Abbild.* livrais ii. pl. 6, and *Beitr.* p. 226.

[4] Numerous nominal species have arisen from the superficial observance of different varieties of this Python. See Russel's *Serpents*, pl. 20, 23, 24, and 29; and Daudin's *Reptiles*, v. pl. 64, fig. 1, and pl. 59, fig. 4.

other species of Python may have attained in ancient times, but it is probably from some misconceived view of our present species that the marvellous traditions regarding almost immeasurable serpents have been derived. Who has not read of that enormous reptile which spread dismay even through a Roman army? It is thus related by Valerius Maximus, from one of the lost books of Livy, by whom it is said to have been recorded at greater length. "And since we are on the subject of uncommon phenomena, we may here mention the serpent so eloquently and accurately (!) recorded by Livy, who says, that near the river Bagrada in Africa, a snake was seen of so enormous a magnitude as to prevent the army of Attilius Regulus from the use of the river; and after snatching up several soldiers with its enormous mouth, and devouring them, and killing several more by striking and squeezing them by the spine of its tail, was at length destroyed by assailing it with all the force of military engines and showers of stones, after it had withstood the attack of their spears and darts; that it was regarded by the whole army as a more formidable enemy than even Carthage itself; and that the whole adjacent region, being tainted with the pestilential effluvia proceeding from its remains, and the waters with its blood, the Roman army was obliged to move its station: he also adds, that the skin of the monster, measuring 120 feet in length, was sent to Rome as a trophy." The learned Frienshemius, having had the advantage of living a thousand years or two after the historian of the Punic war, has given a still more circumstantial account of this bloody broil in his *Supplementa Liviana.* He there informs us, that "it caused so much trouble to Regulus, that he found it necessary to contest the possession of the river with it, by employing the whole force of his army; during which a considerable number of soldiers were lost, while the serpent could neither be vanquished nor wounded, the strong armour of its scales easily repelling the force of all the weapons that were directed against it; upon which recourse was had to battering engines, with which the animal was attacked in the manner of a fortified tower, and was thus at length overpowered. Several discharges were made against it without success, till its *back being broken by an immense stone*" (we admire detailed accounts of ancient actions), "the formidable monster began to lose its powers, and was yet with difficulty destroyed, after having diffused such a horror among the army, that they confessed they would rather attack Carthage itself than such another monster." Probably such another was not then at hand, and we believe has never been seen since; but the anecdote itself holds out great encouragement to modern travellers. It is, we doubt not, to *Python bivittatus* that Bosman and other writers refer, when they mention the religious veneration with which some great African serpents are regarded by the natives. But we must conclude our imperfect notice of this genus by stating, that of the remaining species, *P. Schneideri* (Plate CCCCXLIII. fig. 3, and Plate CCCCXLIV. fig. 5) is found in Malacca, Java, Sumatra, and Amboyna; *P. amethystinus*, in Saparua, a small island opposite Amboyna (a nearly identical kind being found in Timor, Samao, and New Ireland); and *P. Peronii* in New Holland.

Genus ACROCHORDUS. Head rounded, eyes extremely small, rather vertical, pupil orbicular, nostrils tubular, nearly terminal, opening forwards or upwards. Tail strongly prehensile, and, in common with the trunk, compressed. Anal hooks wanting. Whole body covered by small scales, and the abdomen furnished with a kind of keel beset with scales. Teeth as in the Boas proper.

The anomalous reptiles of our present genus may be said to combine the characters of the Boas and sea-serpents. Their dentition resembles that of the former, while the position of the eyes and nostrils, the compact closure of the mouth, compressed form of the body, the existence of the abdominal crest, and absence of anal hooks, assimilate them to the latter. They are, however, easily distinguished by being destitute of poison-fangs. Want of attention to the latter character, and some confused and contradictory data furnished by foreign naturalists, have caused several errors in the arrangement of the species, which are very few in number. They inhabit the intertropical countries of Asia, are extremely aquatic in their propensities, and are externally distinguished by a somewhat sombre colouring,—brown and a yellowish hue being the prevailing tints. The Javanese species, *Acrochordus Javanicus*, is of a deep earthen-brown colour, irregularly marbled. Its form is thick, the head short and obtuse, the tail slender in proportion to the other parts. It attains a total length of eight feet, with the thickness of a man's arm, and was first described by Hornstedt, from a specimen taken in a large pepper-ground near Sangasan in Java.[1] *Ac. fasciatus* is also of a brown colour, but with paler bands upon the sides, the general form much more slender, and the dimensions considerably less.[2] It is more extended in its distribution than the preceding, being found in Pondicherry, New Guinea, Sumatra, Java, and Timor. It forms (it is said erroneously) the genus *Chersydrus* of Baron Cuvier,—the great French naturalist having been informed by M. Leschenhault that the snake in question was extremely poisonous, and dwelt in the beds of the rivers of Java. The accuracy of the former assertion has been since disproved. No other species are distinctly known.

SECOND PRIMARY DIVISION.—VENOMOUS SERPENTS.

Family I.—Colubriform Venomous Serpents.

The poisonous species here assembled, although provided with envenomed fangs, so nearly resemble the Colubers in their general external forms as to be easily mistaken for them by an inexperienced eye. They also partake in some points of the features of the sea-serpents, but are distinguished by wanting the flattened tail; while from the concluding family of venomous serpents *properly so called*, they are kept apart by the bulkier proportions, thick triangular heads, vertical pupils, and carinated scales, which characterize the species last alluded to. At the same time it must be admitted, that those rigorous and distinct demarcations which so many lovers of nature desire to establish, but which so few can find, occur as seldom here as in other departments of zoology,—several species in each family showing a strong tendency of transition towards another.

The reptiles of our present family have a more slenderly elongated form than those of other poisonous groups. Their trunk is in general a good deal drawn out, sometimes cylindrical, or slightly compressed. Their tail, like that of all poisonous species, is rather short, conical, and rounded at the extremity. Their head, almost always of nearly equal dimensions with the neck, is small, short, and obtuse at the extremity. The eyes are rather small, sometimes vertical, the pupil always orbicular. The nostrils, always lateral and rather open, are pierced in a large plate on each side of the muzzle. The scales are not numerous, of medium size, and always smooth,—except in *Naja hæmachates*, in which they seem surmounted by a keel. The abdomen is constantly convex, and furnished with plates of greater or less extent, according to the species. But what particularly characterizes this family is, that all the genera of which it is composed have the crown of the head covered by nine plates,

---

[1] *Act. Stockh.* 1787; and *Journ. de Physique*, 1788.

[2] Shaw, *Gen. Zool.* iii. pl. 130.

nous
nts.

modelled after the type of those of Coluber. The poison apparatus is much less developed than among other venomous kinds; but the fangs, though short, are strong. The species inhabit the warmer countries of both the New and Old World, but do not occur in Europe. They form three generic groups, as after mentioned.

Genus Elaps. Body slender and cylindrical, of nearly equal size throughout, and usually encompassed by fifteen rows of broad, smooth scales. Head elongated, and not strongly distinguishable from the trunk.

This genus was established by Schneider,[1] and now contains all those slender-bodied venomous kinds, which by their elongated forms remind us of *Tortrix and Calamaria.* They attain to no great size, seldom reaching three or four feet in length, and scarcely exceeding a finger's thickness in diameter. Their colours are often bright and beautiful, a combination of red and black being frequent among them. They prefer countries covered by an abundant vegetation, concealing themselves amid the herbs of the meadows, or the loftier luxuriance of the forest; and with this circumstance we may connect the fact, that only a single species is found in Africa, all the others occurring in tropical America, New Holland, the Indian Archipelago, and Bengal,—the latter country however producing likewise only a solitary instance in *Elaps trimaculatus.* Their agility is by no means great, and they prey chiefly on other reptiles,—birds being probably too active, quadrupeds too large, and fish too aquatic, for creatures of slowish movement, small size, and terrestrial habits. We cannot here detail the species, of which eleven are described by M. Schlegel, but must rest satisfied by referring, as examples, to a few figures, such as,—*E. corallinus* (*Nova Acta*, x. pl. 4), *E. Surinamensis* (*Seba*, ii. pl. 86, fig. 2), *E. collaris* (*Erpétol. de Java*, pl. 45), *E. trimaculatus* (Russel, *Ind. Serp.* i. pl. 8).

Genus Bungarus. Form more robust than that of Elaps. Head broad, depressed, rounded terminally, and towards the sides. Abdomen convex. Tail robust. Dorsal line furnished with a row of hexagonal scales, larger than the rest. Sub-caudal plates simple.

To this genus belong the *Bungarum pamma* of Russel (*Ind. Serp.* i. pl. 3), *B. annularis*, Daudin, and the *Geedi Paragoodoo* of the former author, *B. semifasciatus* of Khul and Schlegel. Both species inhabit India, as well as Java and Ceylon. The natives of India, who are said generally to exaggerate the noxious character of their serpents, assert that the bite of the latter produces immediate death, although Dr Russel's experiments go to prove that it is seldom fatal to chickens in less than half an hour, or to dogs in a shorter period than an hour and a half. A *Geedi Paragoodoo* was made to bite a large dog on the thigh, near the groin, where it held fast for more than twenty seconds, but the fangs scarcely penetrated farther than the skin. The dog howled much when first wounded, but on being set at liberty walked about for a time without manifesting any peculiar symptoms. In ten minutes, however, he drew up the wounded leg, continuing to stand on the other three; in a quarter of an hour he crouched, and howled again, and the thigh became paralytic, though the poor creature was still able to raise himself; in twenty-five minutes both thighs were paralytic; and in the course of the second hour he became greatly disordered, grew apparently torpid, lay panting on one side, and died in about two hours, without convulsions. Another dog of smaller size expired in one hour and ten minutes, after being strongly convulsed for some minutes prior to its death.

Genus Naja. General form robust. Body not cylindrical, but thickening in the middle, and tapering towards either end. Tail lengthened and conical. Abdomen broad and convex. Head well distinguished from the trunk. Eyes large and lateral. Neck more or less capable of inflation.

Venomous
Serpents.

This genus contains the famous hooded or spectacle-snakes, called *cobras de capello* by the Portuguese, the majority having the power of raising the anterior ribs, so as to produce a peculiar disk-like inflation of the neck or upper portion of the body. The species are peculiar to the ancient world,—if New Holland, which produces two, and was unknown to the ancients, may be classed therein. M. Schlegel describes eleven different kinds, many of which, however, are arranged in separate genera by other writers, but which that author regards as forming an uninterrupted series, closely connected with each other, and of which the foremost exhibit the announced generic characteristics in great strength and precision, while the others gradually depart from the type, and form a passage to the vipers.

The hooded snake, commonly so called (*Coluber naja* of the older writers,—*Naja tripudians* of the recent systematists), is one of the most noted as well as noxious of the Indian reptiles. Its general length is from three to four feet, and the diameter of its body about an inch and a quarter. The inflated portion is marked above by a large conspicuous patch, closely resembling the figure of an old-fashioned pair of spectacles. The usual colour of the upper parts is pale ferruginous brown, the under being of a bluish white occasionally tinged with yellow. The terminal portion tapers gradually, and ends in a rather slender sharp-pointed extremity. In India this dreaded species is more universally known than any other. It is frequently exhibited as a public show, and being carried about in a covered basket, is made to assume a kind of dancing motion (a modification, we presume, of some natural and instinctive movement) for the amusement of the public. Raising itself up on its lower extremity, and moving its head and body alternately from side to side, the insidious creature seems pleased by keeping time with the measured melody of "flutes and soft recorders." We presume that a love of music is natural to certain serpents; and that this fact was observed of old in Palestine, is probable from the expression of the inspired Psalmist, who compares the ungodly to the deaf adder, which "stoppeth her ears, and refuseth to hear the voice of the charmer." Chateaubriand relates that he was an eyewitness, on the banks of the Genesee, to the fact of a native appeasing the wrath of a rattle-snake (which he even caused to follow him), merely by the music of his flute. The dancing snakes of India are usually, though not universally, deprived of their poison-fangs. "When the music ceases," says Mr Forbes, "the snakes appear motionless; but if not immediately covered up in the basket, the spectators are liable to fatal accidents. Among my drawings is that of a *cobra de capello*, which danced for an hour on the table while I painted it; during which I frequently handled it to observe the beauty of the spots, and especially the spectacles on the hood, not doubting but that its venomous fangs had been previously extracted. But the next morning my upper servant, who was a zealous Mussulman, came to me in great haste, and desired I would instantly retire and praise the Almighty for my good fortune. Not understanding his meaning, I told him that I had already performed my devotions, and had not so many stated prayers as the followers of his prophet. Mohammed then informed me, that while purchasing some fruit in the bazaar, he observed the man who had been with me the preceding evening, entertaining the country people with his dancing snakes; they, according to their usual custom, sat on the ground around him; when, either from the music stopping too suddenly, or from some other cause irritating the vicious reptile which I had often handled, it darted at the throat of a young woman, and inflicted a wound of which she died in half an hour."[2] A similar fate had

---

[1] *Hist. Amphib.* ii. p. 289.

[2] *Oriental Memoirs*, i. p. 44.

Venomous Serpents.

nearly befallen an artist employed by Professor Reinwardt to paint the portrait of a living Naja. It had in some way disengaged its bands, and seemed to have prepared itself to attack the unsuspecting painter the moment he entered his apartment. He there found it supported on its tail, its body raised, its neck dilated, its head advanced,—and then giving utterance to some hissing sounds, it threw a quantity of saliva upon the very man who was about to hand it down to posterity, but who fortunately effected an instantaneous retreat before it came to closer quarters. We doubt not the painter loved the picturesque, although that was not the time to gaze with admiration on the fierce intruder:—

> Not with intended wave,
> Prone on the ground (as since), but on his rear,
> Circular base of rising folds, that tower'd
> Fold above fold, a surging maze! his head
> Crested aloft, and carbuncle his eyes.

Dr Russel informs us that he never knew the bite of a hooded snake prove mortal to a dog in much less than half an hour, although it kills chickens in less than half a minute. Now the rattle-snake has been known to kill a dog in less than two minutes. Yet the use of the lunar caustic, which in the hands of the Abbé Fontana proved so efficacious when applied as remedial to the bite of the viper, was found of little or no avail in India as a counteraction to the venom of the *cobra de capello*.[1] We shall conclude our notices of this species by observing, that the Ceylonese jugglers, according to Dr Davy, use it without extracting the fangs, the only means which they employ to avoid its vengeance being courage and agility. It is in fact held in veneration by the natives of that island, who carefully avoid it, offer it no injury, and put it out of doors unhurt when it happens to enter their dwellings.[2] The root of *Ophiorhyza mungos* is believed in India to be a specific against the bite of the *cobra de capello*.

Another noted species is the *Naja haje* (*Coluber haje*, Linn.), which plays the same part in the history and superstitions of the African tribes as the preceding does in those of the Asiatic nations. The ancient Egyptians named it *Ouro*, a term which signifies king, and which the Greeks adopted into their language in the word *Ouraios*. It is frequently represented in various Egyptian antiquities, whether as drawn in colours, sculptured on the covers of sarcophagi, or cast in bronze. One of the great creative spirits of the world, called Cneph, Cnouphis, or Ammon, in the cosmogony of Egypt, was represented in their symbolical writings under the form of a serpent winding itself around a globe, or placed in the centre of a disk.

The jugglers of modern Egypt, especially of Cairo, use this Naja in their pretended sorceries. These people affect to be descendants of the ancient Psylli, and boast of inheriting from their ancestors the power of subduing and commanding the most poisonous reptiles. The principal feat which they execute consists in making the naja counterfeit death, or they change it into a rod. This they seem to effect by pressing the neck of the creature between their fingers, so as to produce a kind of catalepsy, which renders it stiff and motionless. This is rather a singular fact when considered in connection with the scriptural narrative, where the rods of the magicians, when thrown down, are converted into serpents.[3] According to M. Geoffroy, the species is still sufficiently common in Egypt, occurring both in fields and ditches. " Les cultivateurs sont donc exposés à le rencontrer fréquemment; mais quoiqu'ils n'ignorent pas le danger de sa morsure, sa présence ne les empêche nullement de vaquer à leur travaux ordinaires; connaissant bien les habitudes du redoutable reptile, ils savent qu'ils n'auraient à craindre d'être attaqués par lui, que s'ils venaient à commetre l'imprudence de s'en approcher. En effet, tant qu'ils se tiennent à quelque distance, l'haje se contente de les suivre du regard, en élevant sa tête et en prenant l'attitude dans laquelle les fig. 4 et 5 le represent."[4] The African Naja attains to about the same size as the Asiatic, and greatly resembles it in general aspect; but its neck is less capable of inflation, and its muzzle more conical. It is usually of a yellowish-brown colour above, varied with numerous black and white spots; the under surface whitish, although some individuals exhibit broad black spots or bands on the abdomen. The Cape Naja is regarded by M. Schlegel merely as a climatic variety of that now mentioned.

The Australian species (*Naja porphyrica*) was first described by Dr Shaw.[5] It belongs to the genus *Oplocephalus* of Baron Cuvier, and we place it here on the authority of M. Schlegel. According to M. Lesson, it is greatly dreaded at Port Jackson, and several convicts are said to have died of its bite in a quarter of an hour. It is common in the sandy brushwood of the shores of Botany Bay. Its movements are full of force and vigour, its agility remarkable, and it defends itself when attacked with great hardihood.[6] Another New Holland species is *Naja curta*, described by MM. Quoy and Gaimard, and said to bear resemblance to a viper. It is probably the only Colubriform venomous reptile which exhibits a somewhat vertically elongated pupil.

Family II.—Sea-Serpents.

Our present family is placed here, on the supposition that all the species which it contains are poisonous. Several naturalists, proceeding on certain data given by Dr Russel, have maintained the contrary opinion; but long-continued researches on the part of M. Schlegel have led to the conclusion that there is really no exception to the rule. Great confusion prevails in the synonymy of the species, chiefly owing to the absence of good figures and accurate comparative descriptions,—even Dr Russel's plates, which are the most numerous, being insufficient to lead to a rigorous determination of the species. The specimens themselves are obtained with great difficulty, and are consequently rare in our collections.

We have not sufficiently precise information on which to settle the geographical boundaries of the marine family of serpents. That species occur in the Persian and Arabian Gulfs is by no means improbable; but the fact is inferred rather from some passages in ancient writers than from modern observation; and we know that the authors of antiquity, at least in some instances, mistook certain eel-formed fishes for actual snakes. Schneider indeed[7] (whose competence as a *scholar* no naturalist would dare to doubt) has quoted several classical writers to demonstrate a remote knowledge of sea-serpents; but that knowledge seems too superficially and vaguely expressed to be altogether trusted, or even understood. Ælian comes closer to the point when he says, that " the seas of India produce hydras with flattened tails."[8]

Modern naturalists are believed to be in error who assert their occurrence in the Atlantic Ocean, no proper proof having been yet adduced of any of these species inhabiting the " American Ferry," as we see that world of waters now named, since the steaming days of the British Queen and

omous
pents.

Great Western. M. Schlegel characterizes the statement as an "assertion que je puis contredire avec certitude." Believing that there are more things in heaven and earth than are "dream't of in our philosophy," and desiring to bear in mind the sentiment of the inspired apostle, that "if any man think that he knoweth any thing, he knoweth nothing yet as he ought to know," we shall content ourselves by stating that sea-serpents have not yet been observed in the Atlantic Ocean. M. Schlegel's researches have led him to believe that they are confined "aux mers intertropicales, ou voisines des tropiques, comprises entre le 90me et les 230me degrés de longit. or. du méridien de Ferro."[1] We shall here state the chief of the actual localities. Several species were received by Dr Russel from among the numerous islands called Sunderabunds, which form the delta of the Ganges. The same author likewise obtained many from different points along the coast of Coromandel. Sir Stamford Raffles mentions three species which frequent the coasts of Sumatra.[2] The Dutch voyagers have observed only a single species on the coast of Java, but they have met with several among the Moluccas, near Timor, Banda, and the shores of New Guinea. Dr Strauss transmitted two species from the Celebes. M. Von Siebold observed them to abound in the China Sea, and met with many in the course of his passage from Java to Japan, from the region of the equator as far north as the 27th degree. Eschholtz has incidentally observed,[3] that the fishermen of the Philippine Islands capture *Acrochordus fasciatus* in the Bay of Manilla, and that this reptile cannot move upon the land. Now it so happens that the Acrochordi correctly so called never inhabit the sea; and it may therefore be inferred that the observer last named had in view, not an *Acrochordus*, but a sea-snake or *Hydrophis*. It is long since Dampier told us of those which he saw along the western shores of New Holland;[4] as did afterwards Sir Joseph Banks along the eastern coast, from the 20th to the 10th degree of north latitude. Forster, as Schneider has recorded, found *Hyd. pelamys* abundant near Otaheite.

The habits of these reptiles are indicated here and there by different writers. Dr Russel describes their aquatic movements as active and elegant, but they have scarcely any locomotive power on land, and speedily die when either brought ashore or placed in fresh water. He found in the abdomen of a female Hydrophis nine perfectly formed young, each of which was enclosed in an egg or envelope, from which (the matured condition) it may be inferred that they are viviparous. It would also seem that their manners are milder than those of the generality of poisonous species. Dr Russel, at least, assures us in regard to *Hyd. gracilis*, that no provocation would induce it to bite any object presented to it. Neither could M. Lesson succeed in his disinterested attempts to make *Hyd. pelamys* wound any poultry, though he kindly put them together alive into a copper bathing tub.[5] The observations received from M. Von Siebold by M. Schlegel confirm the belief of other naturalists, that these reptiles, though assuredly dangerous from their poisonous qualities, are not of a highly ferocious nature. The former traveller fell in with vast numbers while sailing from Batavia to Japan, all of the small species, elsewhere so frequent and widely spread, known to naturalists by the specific name of *pelamys*. Their movements were by no means rapid, although they glided through the water with grace and activity, raising their heads from time to time above the waves, for the purpose probably of respiration. Their motion is produced and directed by an action of the tail, accompanied by a lateral and undulating movement of the other parts of the body. They were easily enough entrapped in wooden buckets, and glided through the sailors' hands without attempting to bite them,—the said sailors having probably been previously informed that they were eels. "Le Professeur Reinwardt," says Schlegel, "confirme ce que M. von Siebold rapporte relativement au caractère doux et tranquille de ces animaux."[6] We cannot, however, help thinking that this alleged sweetness of temper and tranquillity are in some measure inconsistent with the cases of the native woman and Lascar already reported in our introductory observations. The comparatively slow movements also do not accord with what we are elsewhere informed by M. Lesson. "Le 27 Juillet," says that naturalist, "par une journée brûlante, nous fûmes pris de calme sur les côtes de la Nouvelle Guinée. De nombreux serpens marins passèrent le long de la corvette, et un embarcation que le capitaine fit mettre à la mer nous permit de les chasser. Nous atteignimes après de longues pursuites une Pelamide, dont l'agilité était extrême, et les mouvemens de natation des plus rapides."[7]

Venomous
Serpents.

We owe some interesting observations on the manners of these marine serpents to M. Peron,[8] although it may be doubted whether that voyager did not occasionally take his notes from too great a distance, especially in reference to size and colour. No other credible author has ever described any of these species as attaining to so great a length as twelve feet; the usual dimensions, we may here observe, varying from two and a half to five feet. However, M. Peron describes those he saw as gliding lightly in great numbers on the surface of the sea, and waging destructive war against a shoal of small herrings, which fled precipitately towards deeper water. The haunts of these snakes are by no means confined to the shallow shores, or even the vicinity of continents or islands, for they are often met with many hundred miles from land. On opening their stomach, our navigator found it filled with small fish, and various marine crustacea; but the reptiles themselves became the frequent prey of sharks, in the interior of which their half-digested remains were often found. It naturally became a subject of surprise, that creatures so light and active should so often fall victims to an enemy of such weight and sluggishness; but after more lengthened observation, a peculiarity in the habits of the former was thought sufficient to account for their capture. These serpents were often seen as if asleep, and floating on the waves, and so profound was their repose, that a large vessel, "with all its bravery on," might pass close by without their being disturbed by its surging prow, its huge furrow, or the loud voices of the garrulous sailors (Frenchmen, of course). M. Peron supposes that it is in this state of lethargy that the lazy sharks swallow them at their leisure. As to the cause of the torpor itself, he naturally enough suggests that it may arise, as among the terrestrial races, from repletion, and the indolence indulged in by all serpents during the digestive process. "Ces reptiles," he adds, "nagent et plongent avec une égale facilité: souvent à l'instant même où nous croyons pouvoir les saisir avec nos filets, ils disparaissaient à nos yeux; et, s'enfonçant à de grandes profondeurs sous les flots, ils restaient une demi-heure et plus sans remonter à leur surface, ou ne paraissaient qu'à de trés-grandes distances du point où nous les avions vus plonger."[9]

The general ground-colour of the majority of these reptiles is yellowish, varying towards green, blue, or white, and often relieved by blackish rings, or broad lozenge-shaped spots, disposed transversely along the dorsal region. The colours seem less subject to variation than among the other Ophidians, and there is no external difference between the sexes. All the species are included by M. Schlegel in the following genus.

[9] *Loc. cit.*

Genus Hydrophis. Head small, uniform with the trunk. Nostrils vertical, of an orbicular form, and capable of being closed by a valve. Eye small, pupil orbicular. Fangs but slightly developed, and always followed by several other teeth, solid though slender. Body tapering towards both extremities. Scales lozenge-shaped or hexagonal, not imbricated, covered by a thin epidermis, and surmounted by a tubercle, of which there are two on the median range of the abdomen. The abdominal scales scarcely larger than the others. Tail broad, flattened laterally, and performing the functions of an oar or rudder. Lungs often prolonged into a reservoir of air as far as the commencement of the caudal region.

Of this genus there are seven species, the particular characters of which we cannot here detail, although their general attributes may be made out from the preceding observations. See Plate CCCCXLIV. fig. 4.

The most common kind is *Hyd. pelamys* of Oken[1] (*Anguis platura*, Linn.), of a comparatively thickish form, the head much elongated, the median line of the abdomen indicated by a suture formed by two rows of scales. It is of a blackish brown above, beneath yellow; the tail, and sometimes the entire body, varied by these colours. It is the most extensively distributed of the genus, being found wherever any sea-snakes occur. It seems to be the black backed hydrus of Shaw (*Hydrus bicolor*, Schneid.); and in India rejoices in the euphonious name of *Nalla Wahlagillee Pam.*[2] Of general occurrence in the Asiatic seas, it is also common round the coasts of Otaheite, where it is relished as an article of food, and known under the title of *Etoonatoree.*

Family III.—Poisonous Serpents properly so called.

The species of this family are the most venomous of all, and may, for the most part, be recognised by something especially repulsive and forbidding in their aspect. Their form is rather thick and heavy, their tail short, their head extremely broad, depressed, and somewhat heart-shaped; rarely protected by plates, but usually covered by scales resembling those of the dorsal region; the eyes are small, deeply seated in the sides of the head, and shaded by projecting superciliary plates, the pupil vertical; the upper lip is inflated, and falls over the lengthened fangs; the body is usually beset by scales of a lanceolated form, surmounted by a ridge, except in one or two species of Trigonocephalus, in which they are smooth.

Their habits and modes of life likewise present some disparities when compared with those of the preceding groups. Being of a lethargic nature and slow of movement, they seldom wander about in search of prey, but keep themselves coiled up till it approaches closely, and then springing upon it by a sudden straightening of the body, they inflict a fatal wound, which needs no repetition. There seems reason to believe that this mode of attack is peculiar to the present family, the other poisonous kinds pursuing their prey, and *holding on* when they have seized it, while the poisonous serpents properly so called are satisfied by sinking their envenomed fangs into the flesh of their victim. Their gape is very wide, their hooks long and sharp, their poison abundant and in a state of high concentration, and the wound is inflicted suddenly, with great force. The result is left to nature, and is in consequence both sure and speedy.

We have said that the poison-fangs are more developed than among the other Ophidians. They alone occupy the maxillaries, being never followed by any small solid teeth, though these occur along the palate and at the extremity of the lower jaw. The nostrils are in some spacious, in others narrow, and vary also in their position. They are followed in certain species by a deep pit or hollow, scooped in the sides of the muzzle, and connected with a broad cavity in the upper maxillaries. This character (of which, however, we know not the function) seems analogous in some measure to the *larmiers* of ruminating quadrupeds, and has been employed for the distribution of these serpents into several groups. Such as are distinguished by this nasal pit inhabit the forests of tropical countries, and consist of two genera, *Trigonocephalus* and *Crotalus*, of which the former (native both to Asia and America) is chiefly found in moist and sombre woods, or places covered by an abundant vegetation; while the latter (peculiar to the western world) prefers a somewhat drier and more barren soil. Such as possess no nasal excavation are comprized in the genus *Viperus*. They affect a more open, sandy soil, and occur exclusively in the ancient continents and New Holland. We shall briefly survey these different groups, in the order now named.

Genus Trigonocephalus. Head, as in other members of the family, heart-shaped or triangular, extremely broad behind, and consequently very distinguishable from the neck. Tail terminated by a conical corneous plate.

The poison apparatus of these reptiles is developed in the highest degree; and as the species sometimes attain a length of five or six feet, they may be regarded as among the most redoubtable of venomous serpents. They all frequent wooded or shady situations, or moist meadows in the immediate vicinity of forest-land. The abdomen is always broad, rather convex, and furnished with plates, which vary, according to the species, from 140 to about 270. The tail is always short, conical, and usually somewhat slender. The sub-caudal plates vary from forty to seventy; and of these some are simple, others divided into two. The body is often marked by large irregular or lozenge-shaped spots upon a brownish or yellowish ground. Some, however, are reddish, others of a greenish hue, and there is frequently a line of deeper hue behind the eye. The species are rare in collections. None occur in Europe or Africa. America and the intertropical countries of Asia produce a large majority. The genus is divisible into two sections, according as the head is covered with scales or with plates.

One of the most noted species of the first section is *Trig. lanceolatus*, a native of the West Indies.[3] The general colour is greenish yellow, paler beneath, and variously marked with specks, spots, and bands of brown. A broad brown line, bordered with white, proceeds from the eye towards the mouth. We have a good account of the habits and history of this reptile from Colonel Moreau de Jonnès.[4] He tells us of one killed by an officer which measured above seven feet and a half in length; and still greater (but perhaps less accurate) measurements are given by Dutertre[5] and Labat.[6] In the bodies of such females as were examined, he found some fifty or sixty young ones, which, when the period of their birth arrives, issue forth completely formed, and much inclined to bite. In the adult state they prey chiefly on rats, which, though not indigenous to these islands, are now in all probability as 10,000 to one compared with the native quadrupeds. The snakes in question omous ents.

Venomous Serpents.

have also multiplied prodigiously in St Lucia and Martinique, where from sixty to eighty may be killed during the cutting of a single field of sugar-cane. According to M. Moreau de Jonnès, they people the marshes, the cultivated grounds, the forests, the banks of rivers, and even the summits of the mountains. The observer just named encountered one on the very edge of the crater of that naked mountain which overhangs the town of St Pierre, in Martinique, at an elevation of more than 5000 feet; and he feared it the more from the excessive lassitude under which he himself at that time laboured. His alarm was not without cause, for only a few days before, a fisherman at the foot of the mountain had been attacked by a similar reptile, which issued from its concealment among the basalts of the shore, and no efforts could save his life. These dreaded serpents are sometimes found in holes made by rats or land-crabs. They also enter hen-roosts and poultry-yards, and sometimes creep into dwelling-houses, chiefly, however, the huts of the negroes. But the sugar-plantations are their favourite places of resort. "Je n'ai jamais trouvé," says our author, "de serpent stationnaire, qu'il ne fût dans une *position offensive.* L'action par laquelle le reptile prend cette position, s'exprimer aux Antilles par le verbe *lover.* Elle consiste à contourner en spirale toute la longueur de son corps, qui forme quatre cercles egaux en diamètre, superposés les uns au dessus des autres, et sous le dernier duquels la queue est placée comme point central d'appui, de resort et de pivot. La tête, qui termine le cercle supérior, est retirée en arrière. Quand l'animal s'élance sur une proie, il fait effort sur la queue, et déroule subitement les quatre cercles qui semblent se débander." This species preys on birds as well as quadrupeds, and the former manifest their hatred by vain and clamorous cries whenever they behold their "arch destroyer." It avoids the brilliant equatorial light, and usually dwells in shaded places, seeking what it may devour chiefly towards sunset, or during cloudy weather.[1] The distribution of this species is rather remarkable. It does not extend throughout the whole of the Antilles, nor is it found even in the majority of those islands. "By a chance equally singular, fortunate, and inexplicable, it is confined to the islands of Martinique, St Lucia, and Beconia alone; and there is no proof, as has been pretended, that it is common in the American continent. Nevertheless, a tradition exists among the Indigenes, that it was introduced into Martinique by the Arronages, a horde which inhabited near the mouth of the Orinoco, and which, impelled by sentiments of hatred and vengeance against the Carribs of that island, made them this fatal present, and let loose in their forests this serpent, which was brought over in calabashes. But according to another popular opinion in the same country, the Trigonocephalus is aboriginal of Martinique, and cannot live elsewhere, not even in Guadaloupe. Some, however, think differently, and explain the phenomenon by the existence of the dog-headed serpent, which is believed to be a Boa, and which, common in Dominica and St Vincent, has delivered these islands from the Trigonocephalus."[2]

Of the second section of this genus, comprising such as have the head covered by plates instead of scales, we may here name *Trig. rhodostoma*, which is of a thicker and more vigorous form than the other species. The body tapers towards either end, the tail is short and acuminated, the abdomen broad, and the back prolonged into a well-marked keel. The colour is reddish brown, paler on the back, the sides adorned by broad, deep, triangular spots, the abdomen white. The summit of the head is black, surrounded by a broad streak of pale red, which descends the sides of the neck to combine with the beautiful rose-colour which tinges the lateral parts of the head, and from which it is separated by a black band proceeding from behind the eye. The iris is of a golden yellow. "L'expression sauvage de sa physiognomie," says M. Schlegel, "est, pour ainsi dire, adoucie par la nature et la conformation des plaques écailleuses qui semblables à celles de la plupart des couleuvres, ont la surface unie et luisante."[3] This species inhabits the western parts of Java, where it conceals itself in tangled vegetation, and makes its way at times into fields and gardens. It preys chiefly on frogs, and is itself attacked by a species of civet cat which occurs in Java. It is greatly dreaded by the natives on account of its deadly poison; and during M. Khul's residence at Buitenzorg, two labourers bitten by it died in five minutes. Although a viviparous reptile, the fœtus is enclosed in a coriaceous envelope, as large as a pigeon's egg. The species is figured by Russel.[4]

The only other example of the genus we need here notice is *Trig. cenchris*, which inhabits the southern provinces of the United States. Its occipital plates are of small dimensions, and are sometimes even wanting. The ground colour is grayish brown, marked by broad transverse bands of a more coppery hue. The abdomen is yellowish, marked by dark irregular spots. The point of the tail is usually black, and all the parts are minutely speckled by that colour. It is a sluggish, slow-moving reptile, very poisonous, but not given to bite, except in self-defence, when it maintains its position courageously. It has been described by different authors under a great variety of names, and by some under more than one at a time.[5] It is the *Mokassin* snake of the Anglo-Americans, thus called on account of the resemblance of its colour to the piece of dress so named by the native tribes. It is figured by M. Daudin.[6]

Genus CROTALUS. This dreaded genus contains the rattle-snakes, and is distinguished from the preceding by a more robust form, a thicker head, and a tail either armed

[2] Griffith's *Animal Kingdom*, ix. 350.

[3] *Phys. des Serpens*, ii. 547.

[4] *Indian Serpents*, ii. pl. 21.

[5] It is both the *brown* and the *black viper* of Catesby's *Carolina*, pl. 44 and 45; it is once figured, and at least twice described, by Dr Shaw, as *Col. Cacodæmon* and *Tisiphone*, *Gen. Zool.* iii. pp. 377 and 406; it is the *Pelias Niger* of Merrem, *Tentamen*, p. 149; and had been previously described by Linnæus as a Boa (*B. Contortrix*, xii. ed. p. 373). M. Schlegel, indeed, supposes that it is also the *Coluber Constrictor* of the great Swedish naturalist. The Boa just named is believed to be identical with the *hog-nosed snake* of Catesby (*Car.* ii. pl. 56), and may be identical with the preceding nominal species, none of which seem to exceed the size of our common viper; but *Col. Constrictor* of America is usually described as of different habits and much larger dimensions. It is the black *snake* of Catesby (*Car.* ii. pl. 48). "This," observes that author, "is a large and very long snake, some being six feet in length. They are all over of a shining black, never changing their colour, and are very nimble and beneficial in killing rats, which they pursue with wonderful agility to the roofs and all parts of houses and barns, where rats are able to run, for which service they are preserved by most of the inhabitants. They are bold and furious, leaping at and biting those that attack them, though no harm ensues, *their bite not being venomous.* It is said in Carolina that they will attack and swallow rattle-snakes. It is certain most or all snakes will devour one another, not only of their own, but of other kinds, which I have often seen; one, after a long struggle, swallowing another but little less than itself. They are the most numerous of all snakes." "Many ridiculous frights," says Mr Pennant, "have happened from this *innocent* reptile. As every one in America is full of the dread of the rattle-snake, they are apt to fly at the sight of any of the serpent kind. This pursues, soon overtakes, and twisting round the legs of the fugitive, soon brings him to the ground; but he happily receives no hurt, but what may result from the fright. All the mischief this species does is to the housewives, for it will skim their milk-pans of the cream, and rob their hen-roosts of all the eggs." (*Arctic Zoology*, Appendix, p. 92.)

[6] *Reptiles*, v. 358, pl. 70, figs. 3 and 4, and 60, fig. 25.

Venomous Serpents.

by a peculiar organ called the rattle, or prolonged into a sharpened point. There are four species, all peculiar to America. These are often confounded, even by systematic writers; and it is by no means easy to apply the general attributes assigned by travellers to the proper species, which no doubt differ from each other.

It seems ascertained, however, that the bite of all these reptiles is extremely dangerous, the slightest prick of their envenomed fangs, in any part of the body well supplied with blood-vessels, being sufficient to kill almost any animal. Laurenti says, that a person bitten by a Crotalus experiences a swelling of the entire body, the tongue becomes prodigiously inflamed, an unextinguishable thirst takes place, the edges of the wound become gangrened, and the unfortunate victim dies in frightful agony in five or six minutes. Different experiments made in Carolina by Captain Hall, are related in the Philosophical Transactions. A rattle-snake, four feet long, was fastened to a stake, and being made to bite three dogs, the first died in less than a quarter of a minute; the second, in convulsions, in about two hours; the third in about three hours. Four days after this, another dog was bitten by the same snake, and died in half a minute; and then a second received the murderous fangs, and died in four minutes. A common black snake, about three feet long, and very vigorous, was next procured. The reptiles bit each other,—the black snake dying in eight minutes, the rattle-snake not seeming in any way affected by its wound. Proceeding upon the supposition that "none but itself could be its parallel," it was then made to inflict a bite on its own body, and this suicidal deceit was followed by the hoped-for consequence,—it died in less than twelve minutes. The story is probably well known to all, though not credited by so many, of a disagreeable kind of an heirloom which once existed in an American family. A man had been bitten through his boots by a rattle-snake, and died. The boots afterwards descended into the successive possession of two other persons, and killed them both,—an envenomed fang having remained sticking in the leather. As usual, we have contradictory accounts of the effects of corresponding causes. We know that an Englishman who was unfortunately bitten by a rattle-snake at Rouen, in 1827, expired in eight hours; yet in the April of that same year, at a meeting of the Academy of Sciences in Paris, Professor Bosc declared that he had *seen* more than thirty persons who had been bitten by rattle-snakes, not one of whom had died. According to Kalm, even the largest animals, such as horses and oxen, die almost instantly. Dogs longer resist this fatal action. Most animals exhibit an instinctive horror on nearing one of these death-dealing creatures. "I have often," says M. Bosc, "amused myself by trying to force my horse and dog to approach one of these animals. But they would sooner have allowed themselves to be knocked down upon the spot than have come near them." Yet Mr Audubon informs us that the mocking-bird of America, so strong and overpowering is the instinct of parental love, does not hesitate to attack the rattle-snake when it approaches too near its nest,—that it will strike it on the head, pick out its eyes, and eventually put it to death.

The so-called *rattle* of these reptiles consists of a series of hollow, vertically flattened, scaly pieces, of which the posterior portion of one fits into the anterior portion of that which follows. They are thus mechanically and somewhat loosely connected together, without being actually joined, so that when shaken they make a rattling or rustling noise, resembling that produced by rumpled parchment. When young there is at first but a single horny portion at the end of the tail, and attached to the last caudal vertebra. Another is formed on the renewal of the skin, pushing its predecessor onwards, so that the first joint, which is closed at the end, continues to be the terminal one. M. Bosc is of opinion that an additional joint is formed every year, and that if the parts in question were not so often broken off accidentally, we might thus determine the age of each individual. They are, however, extremely fragile; and M. Palisot de Beauvois informs us, that he frequently found these rattles lying detached, in the course of his travels in the United States.[1] Their amount sometimes exceeds thirty, but usually ranges from one to thirteen. Some say that the noise may be heard at the distance of a hundred feet, while Bosc and others allege that it is scarcely audible beyond some twelve or fifteen paces. We shall now briefly notice the different species, the names of which, as already hinted, have been frequently transposed by naturalists.

Crotalus horridus inhabits South America, and is known to the Portuguese by the name of *Carcavela.* Its muzzle is covered by three or four pairs of plates. The scales, which are lozenge-shaped, and surmounted by a cutting keel, are disposed in twenty-nine ranges. Abdominal plates 145, sub-caudal twenty-five. The colour of the upper parts is yellowish brown, relieved upon the back by a range of broad, lozenge-shaped spots. This species measures from four to six feet in length, and, dwelling in a sultry clime, continues in a state of activity throughout the year. Some singular peculiarities in its manners are narrated by naturalists. For example, M. Palisot de Beauvois states, that during one of his journeys he observed a rattle-snake lying on the path, and approached it as quietly as possible. When he was about to strike it, it sprung its rattle, opened its mouth very widely, and received into its throat five young ones, each as thick as a goose's quill. After ten minutes' time, believing itself to be out of danger, it opened its mouth, and allowed the exit of the young, which, however, re-entered on a fresh alarm. This curious fact has been testified (if not confirmed) by another French gentleman, M. Guillemart.

Crotalus durissus (Plate CCCCXLIII. figs. 6 and 10) is a more northern species than the preceding, and to it we may refer the numerous observations which have been made by travellers and tourists on the rattle-snakes of North America. It seems to inhabit from the southern side of the Great Lakes as far as Mexico and California, extending westwards to the foot of the Rocky Mountains, but not occurring to the north of the river St Lawrence. It has only one or two pair of plates upon the muzzle, and the keel upon the scales is less developed; the eyes are smaller, the tints deeper, the spots frequently assume the form of bands, and the tail is black. Abdominal plates 170, sub-caudal twenty-two. As this species dwells in districts subjected during winter to the influence of rigorous cold, it creeps in autumn into covered places, or, hiding itself beneath masses of sphagnum, falls into a state of lethargic repose. An individual killed by M. Bosc, and which did not measure more than four feet in length, was found to have a hare in its interior. Its usual food consists of rats, squirrels, and other small Rodentia. This serpent, commonly called the striped rattle-snake, is said to traverse rivers, and even lakes, by inflating its body like a bladder. "The largest rattle-snake," says Catesby, alluding to one or other of these species, "which I ever saw, was about eight feet in length, and weighing between eight and nine pounds. This monster was sliding into the house of Colonel Blake of Carolina, and had certainly taken up his abode there undisturbed, had not the domestic animals alarmed the family with their repeated outcries; the hogs, dogs, and poultry united in their hatred to him, showing the greatest consternation, by erecting their omous pents.

---

[1] Latreille, *Reptiles*, vi. 73.

Venomous Serpents.

bristles and feathers, and expressing their wrath and indignation, surrounded him, but carefully kept their distance, while he, regardless of their threats, glided slowly along." "It is not uncommon," he adds, "to have them come into houses; a very extraordinary instance of which occurred to myself in the same gentleman's house, in the month of February 1723. The servant, in making the bed in a ground room (but few minutes after I left it), on turning down the sheets, discovered a rattle-snake coiled between the sheets in the middle of the bed." According to M. Audubon, the skin of this species is used in making shoes.[1] Mr Say informs us that it inhabits bare and sterile regions, and is often found in the subterranean dwelling of a marmot, *Arctomys Ludoviciana*.[2] M. Becker of Darmstadt placed two rabbits in a cage with this species, one of them being white, the other reddish brown. The fierce reptile, which was lying in a spiral form in the centre, sounded its rattle, and raised and extended its head from time to time, but made no attempt to seize its prey, although repeatedly provoked by its keeper so to do. A black rabbit was then introduced, which it bit instantaneously, and the victim was dead in eight minutes.[3]

Crotalus miliaris is a small species of North America, recognisable by its head clothed with nine well-developed plates. The eyes are large, the general colour a reddish brown, with three ranges of deeper spots. There are twenty-three rows of scales, and the lower plates are, abdominal 131, sub-caudal twenty-six. This snake was observed by Catesby in Carolina, and is described by Mr Say (under the title of *Crot. tergeminus*) as an inhabitant of those lonely sterile plains which stretch between the Mississippi and the Rocky Mountains. It is regarded as more dangerous than the preceding; its small size and peculiar colour prevent its attracting notice, and its rattle is too feeble to be heard at any distance. People are thus apt to tread or even to sit down upon it unawares, and the consequences are as easily imagined as described. It lives on frogs and insects, is by no means timid, but is easily killed by the slightest blow. It was figured long ago both by Seba[4] and Catesby.[5]

Lastly, *Crotalus mutus* differs from the other species in having the tail terminated by a hardened point instead of rattle. Its head is clothed with scales. The back is keeled, and the scales are surmounted by a tubercular ridge. Abdominal plates 227, sub-caudal forty-nine. This great serpent inhabits Cayenne, Essequibo, Surinam, and other parts of South America. It sometimes measures above ten feet in length, and may be regarded as the most gigantic of all poisonous reptiles. In its mode of life it somewhat resembles *Trigonocephalus* (and is in fact described as a species of that genus by Baron Cuvier[6]). But it is essentially a rattle-snake, though destitute of the particular part from which these species derive their general name. It seems the same as that described under the title of *Curucucu* by Marcgrav.[7] Its poison has been experimented on by Dr Hering.[8]

Genus Vipera. Nasal pit wanting. Head usually covered by ridged lanceolated scales. General form thickish, tapering towards each extremity. Tail short and conical.

The species of this genus, greatly restricted since the time of Linnæus, still exhibit a considerable diversity of character when compared among each other. They inhabit either open sandy plains, or desert heaths, where the vegetation is not umbrageous. Hence their abundance in Africa, and their comparative scarcity in other countries. None occurs in America, a few are found in the drier districts of Asia, three inhabit Europe, and one (of a somewhat anomalous nature) is native to New Holland.

The common viper of Great Britain, and of most parts of the Continent (*Vipera berus*, Daudin—*Coluber berus*, Linn.),[9] is the most poisonous of European reptiles. It rarely exceeds two feet in length. The upper portion of the head is protected by a few plate-like scales, somewhat larger than the others. The usual colour is pale ashy brown above, with a space between the eyes, and a patch on each side of the occiput, deep brown or black. A zigzag band of black (composed in some of confluent spots) extends along the back from the nape to the tail; and there is also a parallel row of small black spots on each side. The abdomen and sub-caudal region are steel-blue, sometimes marbled by a yellowish tint, sometimes uniform, or nearly black. The abdominal plates are about a hundred and forty-five,—the sub-caudal about thirty-five. This species is widely spread over the central and northern parts of Europe, but some uncertainty prevails regarding the so-called common viper of Italy and other southern regions. M. Gistl describes the viper of the environs of Munich as having an upturned snout,[10] which is a character of the aspic; and although Metaxa enumerates *Vipera berus* and its varieties as occurring in the Roman territories,[11] others are of opinion that all its alleged localities are doubtful beyond the Alps.[12] It seems, however, to be found in the temperate parts of Siberia, in Russia, Hungary, all Germany, parts of France, Holland, Denmark, Sweden, and, we believe, Norway. Though common in Great Britain, and many of the western isles of Scotland, it is not indigenous in Ireland. Its vertical as well as horizontal range is considerable, for although it affects the low wide heaths of Groninguen, Overyssel, and Friesland, it also occurs on the summit of the Inselberg in Thuringia, at an elevation of nearly three thousand feet above the level of the sea. The viper preys chiefly on mice and insects. A specimen, on the tail of which we inadvertently tramped while crossing a moor in Glenmuick, and which our friend Dr Greville struck down with his umbrella, was found on dissection to have a large field-mouse in its abdomen.

The bite of this reptile is seldom fatal to animals of moderate size. We have several times seen sporting dogs bitten by vipers on the Scotch moors; and although the cheek might swell, and a heaviness of spirits, and disinclination to distant ranging, usually ensued for a few hours, no perceptible effect could be traced on the following day. A sparrow, however, or even a pigeon, dies in a few minutes after being bitten. Sheep usually escape without any serious consequences. Fontana ascertained, that the hundredth part of a grain of poison was sufficient to kill a sparrow, and that a pigeon required six times that amount. From these data he made a calculation, that it would take nearly three grains to kill a man, and as a viper does not carry above two grains of poison in its vesicles, and does not entirely exhaust that quantity, even after many bites, it was concluded that a human being might receive the bite of five or six vipers without dying in consequence. Now this may be all accurately reasoned in its way, but as physiology is by no means a science of calculation, we would not advise any one to try the experiment. Several facts have been recently adduced to prove, that the bite of this reptile is frequently dangerous, and occasionally fatal. Dr Paulet, in his obser-

vations on the viper of Fontainebleau, states, that an infant of seven years and a half, which was bitten beneath the internal malleolus of the right foot, died at the end of seventeen hours,—while another infant, of only two years, which was bitten in the cheek, took two days to die. Dr Hervez de Chegoni mentions the case of a woman, aged sixty-five years, in good health, and of a sound constitution, who having been bitten in the thigh only once by a single viper, expired under the most deplorable symptoms in thirty-seven hours.

The aspic, *Vipera aspis*, is a species nearly allied to the preceding, of which it is by some regarded as a variety, and of which it seems to assume the place in the south-western countries of Europe, extending as far as the island of Sicily.[1] Its form is more slender, its head larger, its top covered by irregularly formed scales, and the muzzle is slightly turned up. The aspic is the species which served the experiments of Redi, Charas, and Fontana. It inhabits the dry and rocky countries of Italy, has been observed in Switzerland, and is common in France from the 49th degree of north latitude, spreading into Savoy, the Pyrenees, and the Mediterranean shores. It is the viper of Fontainebleau, and is also found in the forest of Montmorency; but in Burgundy, and the more northern parts of France, it is replaced by our common viper.

New Holland produces a rare and remarkable species, which some class as generically distinct, under the title of *Acanthophis*. It is of a thickened form, with a slender hard-pointed tail, the upper part of the head protected by nine plates. The eye is surrounded by plates, of which the superciliary are elevated, and inclined towards the top of the head. It is the *Vipera acanthophis* of M. Schlegel,—*Acanthophis cerastinus*, Lacépède.[2] See Plate CCCCXLIV. fig. 8.

A still more remarkable and anomalous species is the famous *Vipera cerastes* of Africa, figured and described by Bruce the traveller,[3] and also in the great French work on Egypt.[4] Its head is very broad, and heart-shaped; its muzzle broad, obtuse, and rounded; its nostrils rather narrow, vertical and terminal; and its scales surmounted by a tubercular ridge. One of the superciliary scales on each side is converted into a projecting horn-like process, curved forwards; and the ancient name *cerastes* is no doubt derived from this peculiar character,—the Greek word κέρας signifying horn.

Cornua prætendens immania fronte cerastes,
Dum torquet spinam sibilat ecce vagus.

It seldom much exceeds a foot in length, and inhabits the sandy deserts of the north of Africa. Its description by Bruce has been so often quoted, that we shall rest satisfied by the reference already given to the writings of that impugned author.

We here close our sketch of this insidious order. But there still remains the singular genus *Cæcilia*, with which Baron Cuvier concludes his classification of Ophidian reptiles, although other naturalists, both prior to and since the publication of his latest system,[5] have arranged it in the Batrachian order, or have even raised it, with the other constituents of that order, to the rank of a distinct and separate class, called AMPHIBIA.[6] As we have already discussed that so-called class in the article REPTILIA of the present work (see *Encyc. Brit.* vol. xix. p. 150), we shall here subjoin the characters of the anomalous reptiles just referred to, as given by the great French anatomist. They form, under the name of NAKED SERPENTS (*Serpens nues*), the third and concluding family of his Ophidian order.

Genus CÆCILIA. Eyes extremely small, almost concealed beneath the skin, sometimes wanting. Skin smooth, viscous, furrowed by annular folds, apparently naked, but exhibiting in its thickness certain slender scales, regularly disposed on many transverse ridges between the wrinkles of the skin. Head depressed, anus nearly terminal, tail consequently short or almost wanting. Ribs too short to surround the trunk. Vertebræ articulated by facets like hollowed cones filled with gelatinous cartilage, as in fishes and some Batrachia; the cranium united to the first vertebra by two tubercles, also as in Batrachian reptiles. The orbits, covered by the maxillary bones, are only pierced by a very small hole; and the bones of the temples cover the temporal fossæ, in such a way that the head exhibits superiorly nothing but a continuous bony buckler. (See Plate CCCCXLIII. fig. 1*d.*) The hyoid bone, composed of three pair of arches, is so constructed as almost to lead to the belief that in early age there were gills. The maxillary and palatine teeth are ranged on two concentric lines, as in the genus Proteus, but are frequently sharp and curved backwards, as in true serpents. The nostrils open at the back part of the palate, and the lower jaw has no moveable pedicle, the tympanic bone being encased with the other bones in the buckler of the cranium. The auricle of the heart is not sufficiently divided to be described as double; but the second lung is rudimentary, as among the genuine Ophidians. The liver is divided into many transverse foliations.

---

[1] Although the title of *Aspic* has been applied to this species, it is not the reptile so named in ancient days, which was not a European species, but more probably the *Naja haje* of Africa.

[4] *Atlas*, pl. 6, fig. 3, vol. xxv. 83.

[5] *Règne Animal*, 2d ed. 1829.

[6] The separation above alluded to, although first precisely expressed by the word *class*, in the writings of M. de Blainville, and subsequently followed in our own country by Messrs Gray, Bell, &c. had been practically effected by several other authors at an earlier period. M. Duméril seems to have been the first to indicate the propriety of placing the genus *Cæcilia* with the Batrachians, and apart from the Ophidian order (*Mémoires de Zoologie et d'Anatomie comparée*, 1807,—"Sur la division des Reptiles Batraciens en familles naturelles"). In like manner, the *Reptilia nuda* of Oppel (as distinguished from his *Reptilia Testudinata*,—Turtles and Tortoises,—and his *Reptilia Squammata*,—Crocodiles, Lizards, and Serpents) is composed of three primary divisions: 1st, APODA (genus *Cæcilia*); 2d, CAUDATA (gen. *Siren*, *Proteus*, *Triton*, *Salamandra*); 3d, ECAUDATA (Frogs, Toads, &c.). His work, *Die Ordnungen, Familien, und Gattungen, der Reptilien, als Prodrom einer Naturgeschichte dorselben*, was published at Munich in 1811. Merrem, whose unfinished publication (*Beitræge zur Naturgeschichte der Amphibien*) appeared at different periods from 1790 to 1821, published the first edition of his *Tentamen Systematis Amphibiorum* in 1800, and a revisal of the same work in 1820. He first partitions his reptiles into two great classes,—PHILODOTA, containing all such as have the body protected by a corneous or coriaceous covering, and BATRACHIA, including the species of which the covering is soft, smooth, and mucous. He then proceeds to subdivide the latter into three great groups,—APODA, SALIENTIA, and GRADENTIA,—which he makes constituently the same as Oppel's APODA, ECAUDATA, and CAUDATA. Then follows M. de Blainville, with his *class* AMPHIBIENS, ou NUDIPELLIFERES (as distinct from other reptiles), consisting of the Batrachians commonly so called, and the genus *Cæcilia*,—the latter forming the Order PSEUDOPHYDIENS. See *Nouv. Bulletin des Sciences de la Soc. Phil.* for July 1816, and the first volume of *Principes d'Anatomie Comparée*, 1822. Mr Gray also views the Batrachian reptiles as a distinct class or great primary division of the Animal Kingdom, adding thereto the genus *Cæcilia*. *Synopsis Reptilium*, and Griffith's *Animal Kingdom*, vol. ix. Appendix, p. 99, 1831. Finally, Mr Bell has likewise arranged our Batrachian reptiles, and the genus in question, in a separate class AMPHIBIA, which he divides into the five following orders, 1st, AMPHIPNEURTA,—*Sirens* and *Protei*; 2d, ANOURA,—*Frogs* and *Toads*; 3d, URODELA,—*Salamanders*; 4th, ABRANCHIA,—gen. *Menopoma* and *Amphiuma*; 5th, APODA,—genus *Cæcilia*. *Encyclopædia of Anatomy and Physiology*, part i. p. 91. It will be perceived that this system differs chiefly from those now enounced, in the placing of two very peculiar American genera,—*Menopoma* and *Amphiuma*, characterized by the absence of gills,—in a separate order, termed ABRANCHIA, from the presumed peculiarity just alluded to. The last-named arrangement is adopted by Mr Swainson, in *Cabinet Cyclopædia*, vol. cxvi. pp. 83 and 339.

We know nothing of the natural history or habits of the animals of this genus. They are said to dwell in marshy ground, several feet below the surface. They probably prey on worms and insects, although vegetable matters, mould, and sand, have been found in their intestines.

In certain species the muzzle is obtuse, the skin loose, the folds conspicuous, and there are two small hairs near the nostrils. To this section belongs *Cæc. annulata* of Spix, a Brazilian species, of subterranean habits. It is of a blackish hue, with upwards of eighty annular folds, and circularly marked with white. The teeth are conical. Others have the folds more numerous, or rather in the form of serrated transverse striæ. Such is *Cæc. glutinosa*, Linn., from Ceylon, a blackish-coloured reptile, marked by a longitudinal band of white on either side, and characterized by 350 folds, which unite beneath in an acute angle. We have figured a nearly allied species from America, *Cæc. bivittata* of the French naturalists (see Plate CCCCXLIV. fig. 3). Finally, a few have the folds almost effaced, the body long and slender, and the muzzle projecting. *Cæc. lumbricoides*, Daudin,[1] is entirely blind, of a blackish colour, two feet long, and not thicker than a quill. Baron Cuvier possessed the skeleton of a Cæcilia more than six feet long.[2] There were 225 vertebræ, but the external characters were unknown. (T.)

SERPENT, a powerful bass musical instrument of the wind kind, invented by a French priest at Auxerre in 1590. See the article MUSIC.

SERPENT, in *Mythology*, was a common symbol of the sun, and he is represented biting his tail, and with his body formed into a circle, in order to indicate the ordinary course of this luminary. The serpent was also the symbol of Medicine, and of the gods which presided over it, as of Apollo and Æsculapius; and this animal was the object of very ancient and general worship, under various appellations and characters. In most of the ancient rites we find some allusion to the serpent, under the several titles of Ob, Ops, Python, and the like. This idolatry is alluded to by Moses. The woman at Endor who had a familiar spirit is called Oub, or Ob, which is interpreted Pythonissa. The place where she resided, says Bryant, seems to have been named from the worship there instituted; for Endor is compounded of *En-ador*, and signifies *fons Pythonis*, "the fountain of light," the oracle of the god Ador, which oracle was probably founded by the Canaanites, and had never been totally suppressed. His pillar was also called *Abbadir* or *Abadir*, compounded of *ab* and *adir*, and meaning the serpent deity Addir, the same as Adorus.

In the orgies of Bacchus, the persons who partook of the ceremony used to carry serpents in their hands, and with horrid screams call upon Eva, being, according to the writer just mentioned, the same as epha or opha, which the Greeks rendered *ophis*, and by it denoted a serpent. These ceremonies and this symbolical worship began among the Magi, who were the sons of Chus; and by them they were propagated in various parts. Wherever the Ammonians founded any places of worship, and introduced their rites, there was generally some story of a serpent. There was a legend about a serpent at Colchis, at Thebes, at Delphi, and at other places. The Greeks called Apollo himself Python, which is the same as Opis, Oupis, and Oub.

In Egypt there was a serpent named Thermuthis, which was looked upon as sacred; and the natives are said to have made use of it as a royal tiara, with which they ornamented the statues of Isis. The kings of Egypt wore high bonnets, terminating in a round ball, and surrounded with figures of asps; and the priests had likewise the representation of serpents upon their bonnets.

Abadon, or Abaddon, mentioned in the Revelations (xx. 2), is supposed by Bryant to have been the name of the Ophite god, with whose worship the world had been so long infected. This worship began among the people of Chaldæa, who built the city of Ophis upon the Tigris, and were greatly addicted to divination and to the worship of the serpent. From Chaldæa the worship passed into Egypt, where the serpent deity was called Canoph, Can-eph, and C-neph. It had also the name of Ob or Oub, and was the same as the Basiliscus or royal serpent, the same as the Thermuthis, and made use of by way of ornament to the statues of their gods. The chief deity of Egypt is said to have been Vulcan, who was styled Opas. He was the same as Osiris, the Sun; and there were pillars sacred to him, with curious hieroglyphical inscriptions bearing the same name, whence, among the Greeks, who copied from the Egyptians, every thing gradually tapering to a point was styled obelos, or obeliscus.

---

[1] *Reptiles*, viii. 92, 2.

[2] *Règne Animal*, ii. 101, note.

As the worship of the serpent began among the sons of Chus, Bryant conjectures, that from thence they were denominated Æthiopians and Aithiopians, from Ath-ope or Ath-opes, the god whom they worshipped, and not from their complexion. The Æthiopes brought these rites into Greece, and called the island where they first established them, *Ellopia, Solis Serpentis insula*, the same with *Eubœa*, or *Oubaia*, "the serpent island." The same learned writer discovers traces of the serpent-worship among the Hyperboreans, at Rhodes, in Phrygia, and upon the Hellespont; in the island Cyprus, in Crete, among the Athenians; in the name of Cecrops, among the natives of Thebes in Bœotia, among the Lacedæmonians, in Italy, in Syria; and in the names of many places, as well as of the people, where the Ophites settled. One of the most early heresies introduced into the Christian church was that of the Ophitæ. (Bryant's Analysis of Ancient Mythology, vol. i. p. 43 and 473.)

SERPENTARIUS, in *Astronomy*, a constellation of the northern hemisphere, called also Ophiuchus, and anciently Æsculapius. The stars in the constellation Serpentarius are, in Ptolemy's catalogue twenty-nine, in Tycho's fifteen, in Hevelius's forty, and in the British catalogue seventy-four.

SERPENTINE, in general, denotes any thing that resembles a serpent. Hence the worm or pipe of a still, twisted in a spiral manner, is termed a *serpentine worm.*

Serpentine *Verses* are such as begin and end with the same word; as,

Ambo florentes ætatibus, Arcades ambo.

Serpentine, in the *Manège.* A horse is said to have a serpentine tongue, if it is always frisking and moving, and sometimes passing over the bit, instead of keeping in the void space called the liberty of the tongue.

SERPOOR, a town of Hindustan, province of Berar, in the nizam's territories, 104 miles south from Nagpoor. Long. 80. 2. E. Lat. 19. 41. N.

SERPUCHOW, a city of European Russia, in the province of Moscow, the capital of a circle of the same name. It stands at the junction of the rivers Nara and Serpeika, which soon after fall into the Oka. It is a place of some trade in corn, tallow, hemp, flax, and wool, which are sent both to Moscow and to St Petersburg. It contains sixteen churches, 780 houses, and 5740 inhabitants. Long. 37. 2. E. Lat. 55. 51. N.

SERRA, a town of Italy, in the Neapolitan province of Calabria Ulteriore I., containing 4830 inhabitants.

Serra di Falco, a town of the Island of Sicily, in the province of Mazzara, situated in a moderately healthy plain, sixty-four miles from Palermo. It contains 3800 inhabitants.

SERRAMANNU, a town of the island of Sardinia, in the diocese of Cagliari. It is situated upon the unhealthy plain of Ippis, and contains 1820 inhabitants.

SERRANUS, Joannes, or *John de Serres*, a learned French Protestant, was born about the middle of the sixteenth century. He acquired the Greek and Latin languages at Lausanne, and devoted himself to the study of the philosophy of Aristotle and of Plato. On his return to France he studied divinity, and in 1574 he began to distinguish himself by his writings, but was obliged to forsake his country after the dreadful massacre of St Bartholomew. He became minister of Nismes in 1582, but was never regarded as a very zealous Calvinist; he has even been suspected, though without reason, of having actually abjured the Protestant religion. He was one of the four clergymen whom Henry IV. consulted about the Catholic religion, and who returned for answer, "that Catholics might be saved." He wrote afterwards a treatise in order to reconcile the two communions, entitled "De Fide Catholica, sive de Principiis Religionis Christianæ, communi omnium Christianorum consensu, semper et ubique ratis." This work was disliked by the Catholics, and received with such indignation by the Calvinists of Geneva, that many writers have affirmed that they poisoned the author. It is certain at least that he died at Geneva in 1598, at the age of fifty. His principal works are, 1. A Latin translation of Plato, published by Henry Stephens; 2. A treatise on the Immortality of the Soul; 3. De Statu Religionis et Republicæ in Francia; 4. Mémoire de la Troisième Guerre Civile et derniers Troubles de France sous Charles IX. &c.; 5. Inventaire Général de l'Histoire de France, illustré par le Conférence de l'Eglise et de l'Empire; 6. Recueil des Choses Memorables avenues en France sous Henri II., François II., Charles IX., Henri III. These three historical treatises have been justly accused of partiality and passion; faults which it is next to impossible for a contemporary writer to avoid, especially if he bore any part in the transactions which he describes. His style is exceedingly incorrect and inelegant; his mistakes and mistatements of facts also are very numerous.

SERRATED, in general, something indented or notched in the manner of a saw; a term much used in the description of the leaves of plants.

SERRA-VALLE, a town of Italy, in the kingdom of Sardinia, in the province of Turin. It is situated on the river Scrivia, has an old castle, four churches, and four monasteries, and a college formerly occupied by the Jesuits. It contains 5420 inhabitants.

SERRAVALLE, a city of the delegation of Treviso, in the Austrian kingdom of Lombardy. It stands on the river Maschio, between two mountains; is the seat of a bishop, has a cathedral and several churches and monasteries, and 5630 inhabitants employed in the silk and woollen manufactories, and some trade in corn, wine, and oil.

SERRIS, a town of Hindustan, in the province of Bahar, eighty miles south-west by south from Patna. Long. 84. 18. E. Lat. 24. 50. N.

SERT, a town of Kurdistan, in Asiatic Turkey, the ancient capital of Tigranes, which was plundered by the Romans under Lucullus, but retained its consequence till after the Saracen invasion. It is now only a large village, containing about 3000 inhabitants, partly Mahommedans and partly Armenian Christians, for whose accommodation there are three small mosques, a college, and an Armenian church. It is situated in a small plain, surrounded by mountains, and is washed by the river Kabour. The chief is a powerful feudal lord. It is seventy-five miles south-east of Diarbekir.

SERVANDONI, John Nicholas, a celebrated architect, was born at Florence in 1695. He rendered himself famous by his exquisite taste in architecture, and by his genius for decorations, fetes, and building. He was employed and rewarded by most of the princes in Europe. In Portugal he was honoured with the order of Christ. In France he was architect and painter to the king, and member of the different academies established for the advancement of these arts. He received the same titles from the kings of Britain, Spain, Poland, and from the Duke of Wirtemberg. Notwithstanding these advantages, his want of economy was so great, that he left nothing behind him. He died at Paris in 1766. Paris is indebted to him for many of its ornaments. He made decorations for the theatres of London and Dresden. The French king's theatre, called *La Salle des Machines*, was under his management for some time. He was permitted to exhibit certain shows, consisting of simple decorations. Some of these were astonishingly sublime; his Descent of Æneas into Hell in particular, and his Enchanted Forest, are well known. He built and embellished a theatre at Chambor for Marshal Saxe, and furnished the plan and the model of the theatre-royal at Dresden. His genius for fetes was remarkable; and he had the management of a great number in Paris, and even in London. He conducted one at Lisbon, given on account of a victory gained by the Duke of Cumberland. He was employed frequently by the king of Portugal, to whom he presented several elegant plans and models. The Prince of Wales, too, the father of George III. engaged him in his service; but the death of that prince prevented the execution of the designs which had been projected. He presided at the magnificent fete given at Vienna on account of the marriage of the Archduke Joseph and the Infanta of Parma. But it would be endless to attempt an enumeration of all his performances and exhibitions.

SERVANT, a term of relation, signifying a person who owes and pays obedience for a certain time to another in quality of a master.

The first sort of servants acknowledged by the laws of England are menial servants, so called from being *intra mœnia*, or domestics. The contract between them and their masters arises upon the hiring.

Another species of servants are called apprentices, from *apprendre*, to learn; and are usually bound for a term of years, by deed indented, or indentures, to serve their masters, and be maintained and instructed by them.

A third species of servants are labourers, who are only hired by the day or the week, and do not live *intra mœnia*, as part of the family.

There is yet a fourth species of servants, if they may be so called, being rather in a superior or ministerial capacity, such as stewards, factors, and bailiffs; whom, however, the law considers as servants *pro tempore*, with regard to such of their acts as affect their master's or employer's property.

SERVETISTS, a name given to the modern Antitrinitarians, from their being supposed to be the followers of Michael Servetus, who, in the year 1553, was burned at Geneva, together with his books.

SERVETUS, MICHAEL, a learned Spanish physician, was born at Villanueva in Aragon, in 1509. He was sent to the university of Toulouse to study the civil law. The Reformation, which had awakened the most polished nations of Europe, directed the attention of thinking men to the errors of the Romish church, and to the study of the Scriptures. Among the rest Servetus applied to this study. From the love of novelty, or the love of truth, he carried his inquiries far beyond the other reformers, and not only renounced the false opinions of the Roman Catholics, but went so far as to question the doctrine of the Trinity. Accordingly, after spending two or three years at Toulouse, he determined to go into Germany to propagate his new opinions, where he could do it with most safety. At Basel he had some conferences with Œcolampadius. He went next to Strasburg to visit Bucer and Capito, two eminent reformers of that town. From Strasburg he went to Hagenau, where, in 1531, he printed a book entitled *De Trinitatis Erroribus*. The ensuing year he published other two treatises on the same subject. In an advertisement to this work he informs the reader that it was not his intention to retract any of his former sentiments, but only to state them in a more distinct and accurate manner. To these two publications he had the courage to put his name, not suspecting that, in an age when liberty of opinion was asserted, the exercise of that liberty would be attended with danger. After publishing these books he left Germany, probably finding his doctrines not so cordially received as he expected. He went first to Basel, and thence to Lyons, where he lived two or three years. He then removed to Paris, where he studied medicine under Sylvius, Fermelius, and other professors, and took the degrees of master of arts and doctor of medicine. His love of controversy involved him in a serious dispute with the physicians of Paris; and he wrote an Apology, which was suppressed by an edict of the parliament. The misunderstanding which this dispute produced with his colleagues, and the chagrin which so unfavourable a termination occasioned, made him leave Paris in disgust. He settled two or three years in Lyons, and engaged with the Frellons, eminent printers of that age, as a corrector of the press. At Lyons he met with Pierre Palmier, the archbishop of Vienne, with whom he had been acquainted at Paris. That prelate, who was a great encourager of learned men, pressed him to accompany him to Vienne, offering him at the same time an apartment in his palace. Servetus accepted the offer, and might have lived a tranquil and happy life at Vienne, if he could have confined his attention to medicine and literature. But the love of controversy, and an eagerness to establish his opinions, always possessed him. At this time Calvin was at the head of the reformed church of Geneva. With Servetus he had been acquainted at Paris, and had there opposed his opinions. For sixteen years Calvin kept up a correspondence with him, endeavouring to reclaim him from his errors. Servetus had read the works of Calvin, but did not think that they merited the high eulogies of the reformers, nor were they sufficient to convince him of his errors. He continued, however, to consult him; and for this purpose sent from Lyons to Geneva three questions, which respected the divinity of Jesus Christ, regeneration, and the necessity of baptism. To these Calvin returned a civil answer. Servetus treated the answer with contempt, and Calvin replied with warmth. From reasoning he had recourse to abusive language; and this produced a polemical hatred, the most implacable disposition in the world. Calvin having obtained some of Servetus's papers, by means, it is said, not very honourable, sent them to Vienne along with the private letters which he had received in the course of their correspondence. The consequence was, that Servetus was arrested; but having escaped from prison, he resolved to retire to Naples, where he hoped to practise medicine with the same reputation which he had so long enjoyed at Vienne. He imprudently took his route through Geneva, though he could not but know that Calvin was his mortal enemy. Calvin informed the magistrates of his arrival; Servetus was apprehended, and appointed to stand trial for heresy and blasphemy. It was a law at Geneva that every accuser should surrender himself a prisoner, that if the charge should be found false, the accuser should suffer the punishment in which he meant to involve the accused. Calvin not choosing to go to prison himself, sent one of his domestics to present the impeachment against Servetus. The articles brought against him were collected from his writings with great care, an employment which took up three days. One of these articles was, "that Servetus had denied that Judæa was a beautiful, rich, and fertile country; and affirmed, on the authority of travellers, that it was poor, barren, and disagreeable." He was also charged with "corrupting the Latin Bible which he was employed to correct at Lyons, by introducing impertinent, trifling, whimsical, and impious notes of his own through every page." But the main article, which was certainly fatal to him, was, "that in the person of Mr Calvin, minister of the word of God in the church of Geneva, he had defamed the doctrine that is preached, uttering all imaginable injurious and blasphemous words against it."

Calvin visited Servetus in prison, and had frequent conferences with him; but finding that, in opposition to all the arguments he could employ, the prisoner remained inflexible in his opinions, he left him to his fate. Before sentence was passed, the magistrates of Geneva consulted the ministers of Basel, of Berne, and Zurich, and, as another account informs us, the magistrates of the Protestant cantons of Switzerland. And to enable them to form a judgment of the criminality of Servetus, they transmitted the writings of Calvin, with his answers. The general opinion was, that Servetus ought to be condemned to death for blasphemy. He was accordingly sentenced to be burned alive on the 27th of October 1553. As he continued alive in the midst of the flames more than two hours, it is said, finding his torment thus protracted, he exclaimed, "Unhappy wretch that I am, will the flames be insufficient to terminate my misery? What, then, will the hundred pieces of gold, and the rich collar, which they took from me, not purchase wood enough to consume me more quickly?" Though the sentence of death was passed against Servetus by the magistrates of Geneva, with the approbation of a great number of the magistrates and ministers of Switzerland, yet it is the opinion of many historians that this dreadful sentence was pronounced at the instigation of Calvin. This act of severity for holding a speculative opinion, however erroneous and absurd, has left a stain on the character of the illustrious reformer, which will attend the name of Calvin as long as history shall preserve it from oblivion. The address which he used in apprehending Servetus, as well as his harshness towards him during his trial, proves that he was as much influenced by personal hatred as by a desire to support the interest of religion, though, no doubt, he believed he was performing a very praiseworthy action. In what practical school were the principles of toleration to be then studied? This intolerant spirit of Calvin and the magistrates of Geneva gave the Papists a favourable opportunity to accuse the Protestants of inconsistency in their principles, which they did not fail to embrace. "How could the magistrates," says the author of the *Dictionnaire des Heresies*, "who acknowledged no infallible interpretation of the Scriptures, condemn Servetus to death because he explained them differently from Calvin; since every man has the privilege to expound the Scripture according to his own judgment, without having recourse to the church? It is a great injustice to condemn a man because he will not submit to the judgment of an enthusiast, who may be wrong as well as himself."

Servetus was a man of great acuteness and learning, and well versed in the arts and sciences. In his own profession his genius exerted itself with success. In his tract entitled *Christianismi Restitutio*, published in 1553, he remarks, that the whole mass of blood passes through the lungs by the pulmonary artery and vein, in opposition to the opinion which was then universally entertained, that the blood passes through the partition which divides the two ventricles. This was an important step towards the discovery of the circulation of the blood.

His works consist of controversial writings concerning the Trinity; an edition of Pagninus's version of the Bible, with a preface and notes; an Apology to the Physicians of Paris; and a book entitled *Ratio Syruporum*. Mosheim has written in Latin an elaborate history of the heresy and misfortunes of Servetus, which was published at Helmstädt in 1728, 4to.

SERVIA, a province of Turkey in Europe, bounded on the north by the rivers Danube and Save, which separate it from Hungary; on the east it is bounded by Bulgaria; on the west by Bosnia; and on the south by Albania and Macedonia. It is about 190 miles in length from east to west, ninety-five in breadth from north to south, and it is divided into four sangiacates. Two of these were ceded to the Christians in 1718, who united them into one. This continued till 1739, when the Turks were victorious, and then they were abandoned to the Turks by the treaty of Belgrade. Belgrade is the capital town.

SERVICE, Choral, in the Romish church, &c. consists of a certain order of antiphonies and psalms sung to what is called *canto fermo* in Italian, *canto llano* in Spanish, and *plain chant* in French. This kind of chant, in its simplest form, consists of slow sounds of equal duration, and without any embellishment, sung in unisons and octaves. In other cases the *canto fermo* is accompanied by Parts in harmony, but always with due regard to a certain *antique* and very simple style of melody and of harmony, which is founded upon the peculiar *tonality* and *cadences* of the *canto fermo*, and without which it loses its characteristic effects. The *canto corale*, or choral chant, is often particularly named *canto Gregoriano*, or Gregorian chant, from the great pains taken by St Gregory, in the sixth century, to improve and to teach to his pupils the oriental church chants derived from the Greeks. St Ambrose before him had introduced the oriental choral chants into the western church of Italy. We believe that there is yet much curious matter for investigation regarding the probable origin of the melodies that constituted the older *canto fermo*, and the nature and character of oriental scales and melodies. See Music. With regard to the tunes introduced into the early reformed church in the time of Luther and Calvin, some curious particulars are to be found in Bayle's *Dictionaire Historique et Critique*, article Marot. The Puritans in England suppressed the church choral service, and permitted psalm-singing only. Charles II. revived the choral service in England. For minute accounts of the origin, progress, and revolutions of this species of music in various Christian churches, the reader may consult Gerbert, *De Cantu et Musica Sacra*, Padre Martini's *Storia*, Hawkins and Burney's Histories of Music. For technicalities, &c. consult, among other works, A. E. Choron's *Méthode de Plain-Chant*, &c. Paris, 1818; and his *Principes pour apprendre le Plain-Chant*, Paris, 1818.

SERVITES, a religious order in the church of Rome, founded about the year 1233, by seven Florentine merchants, who, with the approbation of the bishop of Florence, renounced the world, and lived together in a religious community on Mount Senar, two leagues from that city.

SERVITOR, in the university of Oxford, a student who attends on another for his maintenance and learning.

SERVIUS, Maurus Honoratus, a celebrated grammarian and critic of antiquity, who flourished about the time of Arcadius and Honorius. He is now chiefly known by his Commentaries on Virgil. There is also extant a piece of Servius upon the feet of verses and the quantity of syllables, called *Centimetrum*.

SERWEL, a small district in the province of Caubul, between the 34th and 35th degrees of north latitude. The country is but little known, it never having been explored by Europeans.

SESOSTRIS, Sesoosis, or Sesonchis, the fifteenth sovereign of the eighteenth dynasty of the Egyptians, is called Rameses by Eusebius, and is said to have reigned during the sixteenth century before the Christian era. At his birth his father is said to have collected all the children born at the same time with him, and to have subjected them to an education which he thought best fitted to render them able to assist his son in his future career. When they had reached the age of puberty, he sent them, under the command of his son, to subdue the inhabitants of Arabia, and afterwards to Libya. On his accession to the throne, he first devoted his attention to the internal affairs of his kingdom, and after having divided it into thirty-six nomi, and appointed governors, he commenced a military career, which only ended when he had subdued the greater part of the world. The Æthiopians, the Gangetic Indians, the Scythians, and the Thracians, with the whole of Asia Minor, acknowledged his sway; and, as memorials of his victories, he erected pillars in the various countries he subdued, some of which were seen by Herodotus. On his return to Egypt he narrowly escaped being burnt to death by the treachery of his brother, who was Danaus of Greece. He brought home a large body of captives, whom he employed in the erection of public works, and more particularly in constructing canals. He erected two statues representing himself and his wife before the temple of Hephæstos, which were forty-five feet high; and four representing his sons, which were thirty feet high. At his death he was succeeded by his son Pheros.

SESQUI, a Latin particle, signifying a whole and a half. When joined with *altera*, *terza*, *quarta*, &c. it is much used in the Italian music to express a kind of ratios, particularly several species of triples.

SESQUIALTER, in *Music*, the ratio of 3 : 2 in the numerical calculation of musical intervals. This, and many other old pedantic terms, such as *super-particular* and *superpartient*, &c., employed to express ratios very simple, and easily intelligible under other terms, had better be abandoned entirely in musical nomenclature, which has long been overloaded with such jargon.

Sesqui-alterate, in *Geometry* and *Arithmetic*, is a ratio between two lines, two numbers, or the like, where one of them contains the other once, with the addition of a half.

Thus 6 and 9 are in a sesqui-alterate ratio, since 9 contains 6 once, and 3, which is half of 6, over; and 20 and 30 are in the same, as 30 contains 20 and half 20, or 10.

Sesqui-duplicate *Ratio* is when of two terms the greater contains the less twice, and half the less remains; as 15 and 6, 50 and 20.

Sesqui-tertional *Proportion* is when any number or quantity contains another once and one third.

SESSION, in general, denotes each sitting or assembly of a council, or other body.

Session *of Parliament* is the season or space from its meeting to its prorogation.

Kirk-Session, the name of a petty ecclesiastical court in Scotland.

Sessions for weights and measures. In London, four justices, from among the mayor, recorder, and aldermen, may hold a session to inquire into the offences of selling by false weights and measures, contrary to the statutes; and to receive indictments and punish offenders.

Court of Session. See Scotland.

Court of Quarter-Sessions, an English court that must be held in every county once in every quarter of a year.

SESTERCE, Sestertius, a silver coin in use among the ancient Romans, called also simply *nummus*, and sometimes *nummus sestertius.* The sestertius was the fourth part of the denarius, and originally contained two asses and a half. It was at first denoted by LLS, the two Ls signifying two libræ, and the S half. But the librarii, afterwards converting the two Ls into an H, expressed the sestertius by HS. The word *sestertius* was first introduced by way of abbreviation for *semistertius*, which signifies two and a half of a third, or, literally, only half a third; for in expressing half a third, it was understood that there were two before.

Some authors make two kinds of sesterces, the less, called *sestertius*, in the masculine gender, and the great one, called *sestertium*, in the neuter; the former we have already described, the latter containing a thousand of the other. Others maintain that any such distinction of great and little sesterces was unknown to the Romans. *Sestertius*, say they, was an adjective, and signified, *as sestertius*, or two asses and a half; and when used in the plural, as in *quinquaginta sestertium*, or *sestertia*, it was only by way of abbreviation, and there was also understood *centena millia*, &c.

This matter has been accurately stated by Mr Raper, in the following manner. The substantive to which sestertius referred is either *as* or *pondus;* and *sestertius as* is two asses and a half; *sestertium pondus*, two pondera and a half, or two hundred and fifty denarii. When the denarius passed for ten asses, the sestertius of two asses and a half was the quarter of it; and the Romans continued to keep their accounts in these sesterces long after the denarius passed for sixteen asses, till, growing rich, they found it more convenient to reckon by quarters of the denarius, which they called *nummi*, and used the words *nummus* and *sestertius* indifferently, as synonymous terms, and sometimes both together, as *sestertius nummus.* In this case the word *sestertius*, having lost its original signification, was used as a substantive; for *sestertius nummus* was not two nummi and a half, but a single nummus of four asses. They called any sum under two thousand sesterces so many *sestertii* in the masculine gender; two thousand sesterces they called *duo* or *bina sestertia*, in the neuter, so many quarters making five hundred denarii, which was twice the sestertium; and they said *dena, vicena, &c. sestertia*, till the sum amounted to a thousand sestertia, which was a million of sesterces. But, to avoid ambiguity, they did not use the neuter *sestertium* in the singular number when the whole sum amounted to no more than a thousand sesterces, or one sestertium. They called a million of sesterces *decies nummûm*, or *decies sestertiûm*, for *decies centena millia nummorum*, or *sestertiorum*, in the masculine gender, omitting *centena millia* for the sake of brevity. They likewise called the same sum *decies sestertium*, in the neuter gender, for *decies centies sestertium*, omitting *centies* for the same reason; or simply *decies*, omitting *centena millia sestertiûm*, or *centies sestertium;* and with the numeral adverbs *decies, vicies, centies, millies*, and the like, either *centena millia* or *centies* was always understood. These were their most usual forms of expression, though for *bina, dena, vicena sestertia*, they frequently said *bina, dena, vicena millia nummûm.* If the consular denarius contained sixty troy grains of fine silver, it was worth something more than eightpence farthing and a half sterling; and the as, of sixteen to the denarius, a little more than a halfpenny. To reduce the ancient sesterces of two asses and a half, when the denarius passed for sixteen, to pounds sterling, multiply the given number by 5454, and cut off six figures on the right hand for decimals. To reduce *nummi sestertii*, or quarters of the denarius, to pounds sterling; if the given sum be consular money, multiply it by 8727, and cut off six figures on the right hand for decimals; but for imperial money diminish the said product by one eighth of itself. To be qualified for a Roman knight, an estate of 400,000 *sesterces* was required; and for a senator, one of 800,000.

SESTET, Italian *Sestetto*, a piece of vocal or instrumental music for six voices or six instruments.

SESTOS, a fortress of European Turkey, situated at the entrance of the Hellespont or Dardanelles, twenty-four miles south-west of Gallipoli. This place is famous for the loves of Hero and Leander, sung by the poet Musæus.

SET, or Sets, a term used by the farmers and gardeners to express the young plants of the white thorn and other shrubs, with which they used to raise their quick or quickset hedges. The white thorn is the best of all trees for this purpose; and, under proper regulations, its sets seldom fail to answer the farmer's utmost expectations.

SETCHEOU, a city of China, of the first rank, in the province of Koeitchoo. The inhabitants are extremely rude and ignorant. Long. 108. E. Lat. 27. 10. N.

SETCHING, a city of China, of the first rank, in the province of Quangsee, bordering on Yunan. Long. 105. 54. E. Lat. 24. 17. N.

SETCHUEN, a province of China, on the western frontier. It has on the north Chen-si, on the east and south Houquang and Yunan, and on the west Thibet. It is mountainous, but is fertilized by the great river Yang-tse-kiang. It produces the sugar-cane, silk, orange and lemon trees, and the best rhubarb in China; while in the mountains are found iron, tin, lead, loadstone, and lapis lazuli. It breeds a small but handsome race of horses. The population is estimated by Sir George Staunton at twenty-seven millions.

SETH, the third son of Adam, the father of Enoch, was born 3874 before Christ, and lived 912 years.

SETHIANS, in *Ecclesiastical History*, Christian heretics, who were so called because they paid divine worship to Seth, whom they looked upon as Jesus Christ the son of God, but who was made by a third divinity, and substituted in the room of the two families of Abel and Cain, which had been destroyed by the deluge. These heretics appeared in Egypt in the second century; and as they were addicted to all sorts of debauchery, they did not want followers, and continued in Egypt above two hundred years.

SETON, in *Surgery*, a few horse hairs, small threads, or large packthread, drawn through the skin, chiefly the neck, by means of a large needle or probe, with a view to restore or preserve health.

Experience shows that setons are useful in catarrhs, inflammations, and other disorders, and particularly those of the eyes; to which may be added, severe headachs, with stupor, drowsiness, epilepsies, and even apoplexy itself.

SETTEE, in sea-language, a vessel very common in the Mediterranean, with one deck and a long sharp prow. They carry some two masts, and some of them three, without top-masts. They have generally two masts, equipped with triangular sails, commonly called lateen sails. The least of them are of sixty tons burden. They serve to transport cannon and provisions for ships of war, and the like. These vessels are peculiar to the Mediterranean Sea, and are usually navigated by Italians, Greeks, or Mahommedans.

SETTING, in *Astronomy*, the withdrawing of a star or planet, or its sinking below the horizon. Astronomers and poets make three different kinds of setting of the stars, viz. the cosmical, acronycal, and heliacal.

Setting, in nautical language. To set the land or the sun by the compass, is to observe how the land bears on any point of the compass, or on what point of the compass the sun is; also, when two ships sail in sight of each other, to mark on what point the chased bears, is termed *setting the chase by the compass.*

SETTLE, a town of the parish of Giggleswick, in the wapentake of Staincliff and Ewcross, in the west riding of the county of York, 253 miles from London. Its situation is very romantic, on the river Ribble, among the hills that separate the counties of York and Lancaster. There is a large market-place, well attended on Thursdays. Near the town is the curious phenomenon of an ebbing and flowing well. In the neighbourhood are some curious Roman antiquities. The population amounted in 1821 to 1508, and in 1831 to 1627.

SETUVAL, or St Ubes, as it is called by the English and Dutch sailors that repair to it. This city is a seaport in the province of Estremadura, and the corregimento of its own name, in the kingdom of Portugal. The harbour is five leagues to the eastward of Cape Espichel. It has a shoal-bar, which extends outwards to the distance of half a league. On the western side of the entrance is a peaked height, 1350 feet above the level of the sea. The eastern side is low, with a very narrow passage, so that no written notices can be sufficient to guide the mariner; but the services of a pilot are indispensable, though when entered it is the best harbour in the whole kingdom.

The possession taken of this place by the fleet of the Emperor of Brazil, in the late war of succession in Portugal, led to the conquest of Lisbon, the capital, and then to the submission of the rest of the kingdom.

The chief article of export is salt, from the evaporation of the sea-water by the heat of the sun. There are more than 500 pits on the banks of the river Jabo, where this salt is formed by the hand of nature. The quantity annually collected amounts to about 200,000 tons, nearly one half of which is sent to Ireland, Sweden, Denmark, and Russia. It is stated that from 400 to 500 foreign vessels enter the port annually. Good wine, to the extent of 1800 pipes, is made in the neighbourhood, one half of which is exported. Oranges and lemons also afford articles for foreign trade.

The city contained, a few years ago, five churches, eleven monasteries, a hospital, a poor-house, about 3000 dwelling-houses, and 14,820 inhabitants.

SEVASTOPOL, known formerly by the Turkish name Achtiar, an important naval arsenal and city belonging to Russia, in the peninsula of the Crimea. It is situated at the south-west point, has an extensive and commodious port, and its depth renders it secure at all seasons and during all winds. By a decree of 1804, it was declared that Sevastopol was to be considered thereafter as a port exclusively for the use of the imperial navy; merchant-ships are therefore not admitted, unless forced in by stress of weather, or when requiring repairs from accidents. The fortifications do not surround the city, but it is defended by six strong batteries towards the sea, and has commonly a garrison of 4000 men.

The fleet, whose head-quarters is at this place, consisted in 1793 of eight ships of the line and twelve frigates and smaller vessels; in the year 1817 it had reached twelve ships of the line, carrying 918 guns, four frigates with 164 guns, seventeen brigs, and eighteen smaller vessels; in 1823 it consisted of fourteen ships of the line, ten frigates, and a number of small craft; and in 1838 it had been augmented to sixteen ships of the line, with a large number of frigates, gun-boats, &c.

The city has the appearance of an amphitheatre on the south side of the port: its white walls and gaudy domes, rising amid green trees, give it a peculiarly lively look. The streets are wide and regular, and intersect each other at right angles, but none of them have any pavement. The houses have of late been increasing in number, and are built in the modern style of Italian architecture. A public garden, with terraces rising one above the other, has been lately formed upon a rising elevation in the middle of the town, and has a very pleasing effect.

The place is well supplied with the necessaries, and even the luxuries, of life; but good water is not abundant, and fuel is scarce. The population, ten years ago, amounted to 22,000 persons; not more than one tenth were civil inhabitants. Since that period, with the increase of the marine, the numbers have probably been augmented. The lazaretto is situated in long. 33. 29. E. and lat. 44. 35. N.

SEVEN Islands, a cluster of very small isles, extending along the north coast of the island of Banca, from which they are separated by a navigable channel. Long. 105. 20. E. Lat. 1. 10. S.

SEVENOAKS, a town of the county of Kent, in the lathe of Sutton-at-Hone, and hundred of Codsheath, twenty-three and a half miles from London. It is pleasantly situated on the side and top of a hill. It has a good grammar-school. There is a good market on Saturdays. Adjoining to the town is the magnificent castle and park of Knowle, the ancient seat of the Dukes of Dorset, but now the property of the Earl of Plymouth. The population, including Riverhead and Weald, amounted in 1821 to 3942, and in 1831 to 4709.

SEVEN Stars, a common denomination given to the cluster of stars in the neck of the sign Taurus, the bull, and properly called the *Pleiades.* They are so called from their number, seven, which appear to the naked eye, though some eyes can discover only six of them; but by the aid of telescopes there appears to be a great multitude of them.

SEVENTH, in *Music*, an interval called by the Greeks heptachordon.

SEVERN, a river of England, which rises near Plinlimmon Hill, in Montgomeryshire, and before it enters Shropshire receives about thirty streams, and passes down to Laudring, where it receives the Morda, that flows from Oswestrey. When it arrives at Monford, it receives the river Mon, passing on to Shrewsbury, which it almost surrounds, and then to Bridgeworth; afterwards it runs through the skirts of Staffordshire, enters Worcestershire, and passes by Worcester; then it runs to Tewkesbury, where it joins the Avon, and from thence to Gloucester, keeping a north-westerly course, till it falls into the Bristol Channel. It begins to be navigable for boats at Welchpool, in Montgomeryshire, and takes in several other rivers in its course, besides those already mentioned, and is the second in England. By means of inland navigation, it has communication with the rivers Mersey, Dee, Ribble, Ouse, Trent, Derwent, Humber, Thames, and Avon; which navigation, including its windings, extends above five hundred miles in the counties of Lincoln, Nottingham, York, Lancaster, Westmoreland, Chester, Stafford, Warwick, Leicester, Oxford, and Worcester. A canal from Stroudwater, a branch of the Severn, to join the Thames, was projected and executed for the purpose of conveying a tunnel sixteen feet high and sixteen feet wide, under Sapperton Hill and Hayley Wood, for two miles and a quarter in length, through a very hard rock, which was lined and arched with brick. This stupendous undertaking was completed, and boats passed through it the 21st of May 1789. By this opening a communication is made between the river Severn at Framiload and the Thames near Lechlade, and is continued over the Thames near Inglesham, into deep water in the Thames below St John Bridge, and so to Oxford and London, for conveyance of coals and goods.

SEVERNDROOG, a small rocky island of Hindustan, on the coast of the Concan, joined to the continent by a reef of rocks, which forms a safe bay for vessels on the south side. This place was taken by the Mahrattas from the king of Bejapore; but his admiral revolting from their authority, it became the head-quarters of a gang of pirates. It was taken by the British in 1756. Long. 73. 13. E. Lat. 17. 47. N.

SEVERUS, CORNELIUS, an ancient Latin poet of the Augustan age, whose *Ætna*, together with a fragment *De Morte Ciceronis*, were published, with notes and a prose interpretation, by Le Clerc, Amsterdam, 1703, in 12mo. They were before inserted among the *Catalecta Virgilii*, published by Scaliger, whose notes, with others, Le Clerc has received among his own.

SEVERUS's *Wall*, in British topography, the fourth and last barrier erected by the Romans against the incursions of the North Britons.

We learn from several hints in the Roman historians, that the country between the walls of Hadrian and Antoninus continued to be a scene of perpetual war and contention between the Romans and Britons, from the beginning of the reign of Commodus to the arrival of the Emperor Septimius Severus in Britain, in the year 206. This last emperor having subdued the Mæatæ, and repulsed the Caledonians, determined to erect a stronger and more impenetrable barrier than any of the former, against their future incursions.

Though neither Dio nor Herodian make any mention of a wall built by Severus in Britain for the protection of the Roman province, yet we have abundant evidence from other writers of equal authority that he really built such a wall. "He fortified Britain," says Spartian, "with a wall drawn cross the island from sea to sea, which is the greatest glory of his reign. After the wall was finished, he retired to the next station (York), not only a conqueror, but the founder of an eternal peace." To the same purpose Aurelius Victor and Orosius, to say nothing of Eutropius and Cassiodorus: "Having repelled the enemy in Britain, he fortified the country, which was suited to that purpose, with a wall drawn cross the island from sea to sea." "Severus drew a great ditch, and built a strong wall, fortified with several turrets, from sea to sea, to protect that part of the island which he had recovered from the yet unconquered nations." As the residence of the Emperor Severus in Britain was not quite four years, it is probable that the two last of them were employed in building this wall; according to which account, it was begun in the year 209, and finished in the year 211.

Severus's Wall.

This wall of Severus was built nearly on the same track with Hadrian's rampart, at the distance only of a few paces north. The length of this wall, from Cousin's House, near the mouth of the river Tyne on the east, to Boulness on the Solway Frith on the west, has been found, from two actual mensurations, to be a little more than sixty-eight English miles, and a little less than seventy-four Roman miles. To the north of the wall was a broad and deep ditch, the original dimensions of which cannot now be ascertained, only it seems to have been larger than that of Hadrian. The wall itself, which stood on the south brink of the ditch, was built of freestone; and where the foundation was not good, it is built on piles of oak. The interstices between the two faces of this wall are filled with broad thin stones, placed not perpendicularly, but obliquely on their edges; and the running mortar or cement was then poured upon them, which, by its great strength and tenacity, bound the whole together, and made it firm as a rock. But though these materials are sufficiently known, it is not easy to guess where they were procured, for many parts of the wall are at a great distance from any quarry of freestone; and though stone of another kind was within reach, yet it does not appear to have been anywhere used. The height of this wall was twelve feet besides the parapet, and its breadth eight feet, according to Bede, who lived only at a small distance from the east end of it, and in whose time it was in many places almost quite entire. Such was the wall erected by the command and under the direction of the Emperor Severus in the north of England; and, considering the length, breadth, height, and solidity, it was certainly a work of great magnificence and prodigious labour. But the wall itself was but a part, and not the most extraordinary part, of this work. The great number and different kinds of fortresses which were built along the line of it for its defence, and the military ways with which it was attended, are still more worthy of our admiration, and come now to be described.

The fortresses which were erected along the line of Severus's wall for its defence were of three different kinds, and three different degrees of strength; and were called by three different Latin words, which may be translated *stations*, *castles*, and *turrets*. Of each of these in their order.

The *stationes*, stations, were so called from their stability, and the stated residence of garrisons. They were also called *castra*, which has been converted into *chestres*, a name which many of them still bear. These were by far the largest, strongest, and most magnificent of the fortresses which were built upon the wall, and were designed for the head-quarters of the cohorts of troops which were placed there in garrison, and whence detachments were sent into the adjoining castles and turrets. These stations, as appears from the vestiges of them which are still visible, were not all exactly of the same figure nor of the same dimensions; some of them being exactly squares, and others oblong, and some, again, a little larger than others. These variations were no doubt occasioned by the difference of situation, and other circumstances. The stations were fortified with deep ditches and strong walls, the wall itself coin-

Severus's Wall.

ciding with and forming the north wall of each station. Within the stations were lodgings for the officers and soldiers in garrison; the smallest of them being sufficient to contain a cohort, or six hundred men. Without the walls of each station was a town, inhabited by labourers, artificers, and others, both Romans and Britons, who chose to dwell under the protection of these fortresses. The number of the stations upon the wall was eighteen; and if they had been placed at equal distances, the interval between every two of them would have been four miles and a few paces. But the intervention of rivers, marshes, and mountains, the conveniency of situations for strength, prospect, and water, and many other circumstances to us unknown, determined them to place these stations at unequal distances. The situation which was always chosen by the Romans, both here and everywhere else in Britain where they could obtain it, was the gentle declivity of a hill, near a river, and facing the meridian sun. Such was the situation of the far greatest part of the stations on this wall. In general, we may observe, that the stations stood thickest near the two ends and in the middle, probably because the danger of invasion was greatest in these places. But the reader will form a clearer idea of the number of these stations, their Latin and English names, their situation and distance from one another, by inspecting the following table, than we can give with equal brevity in any other way. The first column contains the number of the station, reckoning from east to west; the second contains its Latin, and the third its English name; and the three last its distance from the next station to the west of it, in miles, furlongs, and chains.

		Length of the wall	68	3	3

The *castella*, or castles, were the second kind of fortifications which were built along the line of this wall for its defence. These castles were neither so large nor so strong as the stations, but much more numerous, being no fewer than eighty-one. The shape and dimensions of the castles, as appears from the foundations of many of them which are still visible, were exact squares of sixty-six feet every way. They were fortified on every side with thick and lofty walls, but without any ditch, except on the north side, on which the wall itself, raised much above its usual height, with the ditch attending it, formed the fortification. The castles were situated in the intervals between the stations, at the distance of about seven furlongs from each other, though particular circumstances sometimes occasioned a little variation. In these castles guards were constantly kept, by a competent number of men detached from the nearest stations.

The *turres*, or turrets, were the third and last kind of fortifications on the wall. These were still much smaller than the castles, and formed only a square of about twelve feet, standing out of the wall, on its south side. Being so small, they are more entirely ruined than the stations and castles, which makes it difficult to discover their exact number. They stood in the intervals between the castles; and from the faint vestiges of a few of them, it is conjectured that there were four of them between every two castles, at the distance of about three hundred yards from one another. According to this conjecture, the number of the turrets amounted to three hundred and twenty-four. They were designed for watch-towers and places for sentinels, who, being within hearing of one another, could convey an alarm or piece of intelligence to all parts of the wall in a very little time.

Sever Wa

Such were the stations, castles, and turrets, on the wall of Severus; and a very considerable body of troops was constantly quartered in them for its defence. The usual complement allowed for this service was as follows:

1. Twelve cohorts of foot, consisting of 600 men each..	7,200
2. One cohort of mariners in the station at Boulness...	600
3. One detachment of Moors, probably equal to a cohort...	600
4. Four alæ or wings of horse, consisting, at the lowest computation, of 400 each..............................	1,600
	10,000

For the conveniency of marching these troops from one part of the wall to another, with the greater ease and expedition, on any service, it was attended with two military ways, paved with square stones, in the most solid and beautiful manner. One of these ways was smaller, and the other larger. The smaller military way run close along the south side of the wall, from turret to turret, and castle to castle, for the use of the soldiers in relieving their guards and sentinels, and such services. The larger way did not keep so near the wall, nor touch at the turrets or castles, but pursued the most direct course from one station to another, and was designed for the convenience of marching larger bodies of troops.

It is to be regretted that we cannot gratify the reader's curiosity, by informing him by what particular bodies of Roman troops the several parts of this great work were executed, as we were enabled to do from inscriptions with regard to the wall of Antoninus Pius. For though it is probable that there were stones with inscriptions of the same kind, mentioning the several bodies of troops, and the quantity of work performed by each of them, originally inserted in the face of this wall, yet none of them are now to be found. There have indeed been discovered, in or near the ruins of this wall, a great number of small square stones, with very short, and generally imperfect, inscriptions upon them, mentioning particular legions, cohorts, and centuries, but without directly asserting that they had built any part of the wall, or naming any number of paces. Of these inscriptions the reader may see no fewer than twenty-nine among the Northumberland and Cumberland inscriptions in Horsley's *Britannia Romana*. As the stones on which these inscriptions are cut are of the same shape and size with the other facing-stones of this wall, it is almost certain that they have been originally placed in the face of it. It is equally certain, from the uniformity of these inscriptions, that they were all intended to intimate some one thing, and nothing so probable as that the adjacent wall was built by the troops mentioned in them. This was perhaps so well understood, that it was not thought necessary to be expressed; and the distance of these inscriptions from one another showed the quantity of work performed. If this was really the case, we know in general that this great work was executed by the second and sixth legions, these being the only legions mentioned in these inscriptions.

Now, if this prodigious wall, with all its appendages of ditches, stations, castles, turrets, and military ways, was executed in the space of two years by two legions only, which, when most complete, required no less than 12,000 men, how greatly must we admire the skill, the industry, and excellent discipline of the Roman soldiers, who were not only the valiant guardians of the empire in times of war, but its most active and useful members in times of peace?

This wall of Severus, and its fortresses, proved an impenetrable barrier to the Roman territories for nearly two hundred years. But about the beginning of the fifth century, the Roman empire being assaulted on all sides, and the bulk of their forces withdrawn from Britain, the Mæatæ and Caledonians, now called Scots and Picts, became more daring; and some of them breaking through the wall, and others sailing round the ends of it, they carried their ravages into the very heart of provincial Britain. These invaders were indeed several times repulsed after this, by the Roman legions sent to the relief of the Britons. The last of these legions, under the command of Gallio of Ravenna, having, with the assistance of the Britons, thoroughly repaired the breaches of Severus's wall and its fortresses, and exhorted the Britons to make a brave defence, took their final farewell of Britain. It soon appeared that the strongest walls and ramparts are no security to an undisciplined and dastardly rabble, as the unhappy Britons then were. The Scots and Picts met with little resistance in breaking through the wall, while the towns and castles were tamely abandoned to their destructive rage. In many places they levelled it with the ground, that it might prove no obstruction to their future inroads. From this time no attempts were ever made to repair this noble work. Its beauty and grandeur procured it no respect in the dark and tasteless ages which succeeded. It became the common quarry, for more than a thousand years, out of which all the towns and villages around were built; and is now so entirely ruined, that the penetrating eyes of the most poring and patient antiquary can hardly trace its vanishing foundations.

SEVIGNE', Marie de Rabutin, Marquise de, a French lady, was born in 1626. When only a year old she lost her father, who was killed in the descent of the English on the isle of Rhé, where he commanded a company of volunteers. In 1644 she married the Marquis of Sevigné, who was slain in a duel by the Chevalier d'Albret, in 1651. She had by him a son and a daughter, to the education of whom she afterwards religiously devoted herself. Her daughter was married in 1669 to the Count de Grignan, who conducted her to Provence. Madame de Sevigné consoled herself by writing frequent letters to her daughter, but she fell at last the victim to her maternal tenderness. In one of her visits to Grignan, she fatigued herself so much during the sickness of her daughter, that she was seized with a fever, which carried her off on the 14th of January 1696. We have two portraits of Madame de Sevigné; the one by the Comte de Bussi, and the other by Madame de la Fayette. The first exhibits her defects, the second her excellencies. Bussi describes her as a lively gay coquette, a lover of flattery, fond of titles, honour, and distinction; M. de la Fayette, as a woman of wit and good sense, as possessed of a noble soul, formed for dispensing benefits, incapable of debasing herself by avarice, and blessed with a generous, obliging, and faithful heart. Both these portraits are in some measure just. That she was vain-glorious, appears evident from her own letters, which, on the other hand, exhibit undoubted proofs of her virtue and goodness of heart.

This illustrious lady was acquainted with all the wits of her age. It is said that she decided the famous dispute between Perrault and Boileau concerning the preference of the ancients to the moderns. She left behind her a most valuable collection of letters, the best edition of which is that of 1775, in eight volumes 12mo. "These letters," says Voltaire, "are filled with anecdotes, written with freedom, and in a natural and animated style; are an excellent criticism on studied letters of wit, and still more on those fictitious letters which aim at the epistolary style, by a recital of false sentiments and feigned adventures to an imaginary correspondent." It were to be wished that a proper selection had been made of these letters. It is difficult to read eight volumes of letters, which, though inimitably written, present frequent repetitions, and are often filled with trifles. What makes them in general perhaps so interesting is, that they are in part historical. They may be looked on as a relation of the manners, the tone, the genius, the fashions, the etiquette, which reigned in the court of Louis XIV. They also contain many curious anecdotes nowhere else to be found. But these excellencies would be still more striking, were they sometimes stripped of that multitude of domestic affairs and minute incidents which ought naturally to have died with the mother and the daughter. A volume entitled *Sevigniana* was published at Paris in 1756, which is nothing more than a collection of the fine sentiments, literary and historical anecdotes, and moral apophthegms scattered throughout these letters.

Seville.

SEVILLE, the largest, the richest, and most populous of the four kingdoms or provinces of Andalusia, in Spain. Its extent is 752 square miles, and its population amounts to 970,087 souls. It is bounded on the east by Granada and Cordova, on the north by Estremadura, on the west by Portugal, and on the south by the Mediterranean Sea.

The principal river of this province is the Guadalquivir, which, rising in the southern part of New Castille, passes through the whole of the province. This river is navigable for small ships up to the centre of the capital, and much higher for boats and small craft. Below Seville the Guadalquivir is divided into three branches, forming large islands between them, after passing which it unites and enters the ocean at St Lucar.

A great portion of this province is very mountainous. Next to the mountains of Ronda, the loftiest and most picturesque are the Trocha, to the westward of Algesiras, and those on which the city of Medina is situated, and a part of the Sierra Morena. Although these mountains are for the most part uninhabited and uncultivated, yet they afford excellent pasture for sheep during the winter season, when all is bare in the north of Spain. In the valleys is found the most extensive plains of the richest alluvial land, which, though frequently so burnt up by the heat of the summer sun as to display no traces of vegetation, yet, after two or three days of autumnal rain, produce the very richest pasture. As no hay is made in any part of Andalusia, the greatest distress is experienced by the farmers in keeping their cattle through the summer months, and at that period they feed mostly on broken straw, and become very lean; but after the autumnal rains the verdure is abundant, and the cattle become fat. Though the province of Seville does not grow corn sufficient for its own consumption, yet considerable quantities of wheat and barley are produced. The former grain is generally sown after a fallow, which may be made by about three ploughings in the summer months. Where they have manure, as is the case near the large towns, the increase is very great; and where they have not, the fallow alone will produce a very fair crop. The rotation of crops is little attended to. Clover and turnips are not cultivated. The harvest generally takes place in the latter end of June or beginning of July, when the weather is invariably fine. As soon as the wheat is cut, it is thrashed in the field where it is grown. This is done by piling the sheaves on a floor of round pebbles in the open air; and a number of unbroken mares, with a long rein held by a driver, are galloped in a circle over the sheaves. By this operation, from the dry state of the corn, it is easily separated, and the straw is broken into small fragments. They then wait till the wind rises, when the breeze performs the operation of separating the grain from the chaff and broken straw. The former is sent to the granary in a kind of rush paniers on the backs of asses, and the latter is made into a clumsy stack in the field, and kept there for food in the dry season. The barley sown in the spring is most rapid in its growth: sometimes in less than twelve weeks from the period of its being sown, it is cut, thrashed, and fit for the market. But grain is not the most important branch of rural economy in this province. Oil, the substitute for butter in warm climates, is the chief dependence of the Andalusian farmer, and the cultivation of it is more congenial to the indolent habits of the natives. The trees only require planting, and will then yield their produce for ages, with but little attention on the part of the proprietors. The oil, though an important article, and the chief source of the wealth of the province, is not made with much attention either to its cleanliness or its sweetness. The oils of Spain are inferior to those of France and Italy, though the olives from which they are made are decidedly superior. Wines are made to a considerable extent in this province, but not sufficient for its consumption.

Few articles of husbandry are of more universal attention than garlic, which grows in prodigious quantities, and forms in all the markets of Andalusia the most prominent object. The capsicum, or pimento, is also much in demand, and is used in almost every culinary preparation. Instead of hedges formed by thorn bushes, the enclosures are secured by the aloe plant, which makes excellent fences, and, by their sharp points, are a security against all cattle. Instead of orchards of apples and pears, nothing is seen but oranges, lemons, pomegranates, and other fruits of a southern climate.

One production, not alimentary, is of vast importance, and is sedulously cultivated, the Spanish broom or esparto, which is made into a variety of articles for domestic uses.

The breed of horses in Andalusia has at all times been very highly esteemed; they have in them a considerable mixture of the Arabian breed. As cows are not kept for the purposes of the dairy, they are rather neglected, and the breed is by no means good. The sheep are numerous; those of the merino kind are migratory, and belong rather to the whole kingdom of Spain than to this particular province. There are, however, large flocks on the mountains; but as their propagation is left in a great measure to nature, neither their flesh nor their wool is very good.

Some of the largest estates in the province belong to convents, cathedrals, or municipal corporations: they are frequently let to tenants, who pay rent in a portion of the produce. The richer inhabitants in all parts of the peninsula prefer mules to horses for drawing their carriages; and they are used by the corps of artillery in the military service, where they can be procured, in preference to horses.

Besides its agricultural riches, this province is stored with mineral wealth to a great degree. It is well known that the Romans drew from this district, then called Betica, a great portion of their silver; and it continued equally productive during the power of the Arabian race; but the discovery of America, an event contemporaneous with the final extinction of the Moorish government, rendered the industry applied to mining less productive, and in consequence it has greatly diminished. There are, however, mines of silver, copper, mercury, lead, and iron, still worked. The commerce and manufactures of this province are almost wholly confined to the cities of Cadiz and Seville. The inhabitants are estimated at 746,221. It possesses the laws and privileges of Castille. The captain-general resides at Puerto Maria, but there is a royal audienza at Seville.

Seville, a city of Spain, the capital of the province of the same name, and formerly the capital of the ancient kingdom of Aragon. Its origin is unknown; but, under the Roman government, it was a place of considerable note under the name Hispalis. It enjoys a most delightful climate, and is surrounded by a fruitful country. It contains about 100,000 inhabitants, exclusive of the suburb Triana, divided from it by the river. The population of the latter is about 15,000.

Seville abounds with ancient buildings, both Roman and Moorish, and with numerous modern structures of great extent and magnificence. The golden tower, on the banks of the river, is said to have been the work of Julius Cæsar. It is in perfect repair, and, before Cadiz rose to its present importance, the gold and silver transmitted from America was landed here, and deposited in this tower, on account of its strength and security. The aqueduct which supplies the city with spring-water is the work of the same people. It is still in perfect repair, and now, after the lapse of ages, serves the purpose for which it was originally constructed. In the vicinity of the city, at the ancient town of Italica, the birthplace of the Emperor Trajan, are the remains of an ancient amphitheatre, which, though partly in ruins, is sufficiently perfect to show its plan and extent; and from the rows of benches for spectators, which remain, it may be calculated that it would seat about ten thousand persons. Its dilapidated condition is the result of an earthquake, and has not been occasioned by the regular decay of time.

The chief building of the Moorish period that remains is the alcazar or palace: the date of its origin is not ascertained. A considerable part was added by Peter the Cruel, between the years 1353 and 1364. In the addition, the Arabian style of building is so closely imitated, that it is impossible to determine which part was built first. Though the exterior is mean, like all the Arabian buildings, yet the inside is beautifully filled up with noble staircases, marble halls, and courts with fountains of pure and cool water. Before the French entered Andalusia, the central junta occupied the palace after their dispersion. Joseph Bonaparte held his court in it.

Some of the houses of this city, belonging to individuals, have the most entire specimens of the exquisite stucco workmanship with which the rich Moors adorned the interior of their houses. In some of the most obscure streets of the city are found houses with the exterior appearance of a prison, with no windows towards the town, and only an entrance through massy doors studded or plated with iron; but the visiter, on entering, is surprised with the view of arcades surrounded with marble courts and sparkling fountains, and the whole adorned with that durable kind of stucco, in the composition of which the Moors so greatly excelled.

The buildings erected in Seville since the extirpation of the Moors are materially different in their style of architecture. One of these is the cathedral, with its tower, the Giralda, 360 feet in height. The length of this church is 398, and the breadth 290; but its choir and principal altar being in the centre, they take off very considerably from the effect of its dimensions. The different specimens of architecture which in successive periods have prevailed in Spain, may all be seen in this extraordinary church. The tower, and a part called the orange court, *Patio de las Narangas*, was built about the year 1000, by the Moors, and in their peculiar style; another part, built 200 years later, is in the Gothic taste, which was then introduced into Spain; whilst the part which completed it, and which was finished about the year 1520, is in a style denominated by Spanish artists *platareca*, or the imitation of the silver ornaments of a Catholic church. Though this last fashion is a most gross perversion of taste, yet the contrast with the Gothic is not unpleasing; and, viewed as a whole, the cathedral is perhaps one of the grandest of all the modern edifices in the Peninsula.

La Lonja, or the Exchange, for it was designed, though never used, for that purpose, was completed in 1598, and is a most extensive and chaste building, now used as a depository for state-papers, in which are collected all the original despatches from America at the period of its discovery, and the library of the son of Columbus. The college of the Jesuits, since converted into the inquisition, is a most beautiful pile of building, with a handsome church, a hall of judgment, and various cells for the reception of prisoners.

This city abounds in convents, monasteries, and other religious establishments, most of them richly endowed; and their chapels are the repositories of the finest specimens of the art of painting, at the period which produced better artists in Spain than in any other part of Europe. The works of the native artists Murillo, Velasquez, Zubaran, Spanioletti, Morales, Cano, and others, as well as of Titian, Rubens, Michel Angelo, and other foreigners, are preserved in the cathedral, and in several of the other churches, chapels, and convents.

There is a university, though the building is gloomy and tasteless, and the professors neither enlightened or learned; the number of pupils is very considerable, and most of them are destined for the ecclesiastical profession. It is said that two thirds of the houses in this city are either the property of the cathedral or other ecclesiastical bodies, who receive the rents of them in some cases weekly, and in others monthly.

In this city the edifices belonging to the government are numerous and extensive. The mint is one of them, in which the whole process of coining money is conducted. There is a foundery for cannon, a manufactory for muskets, swords, and other military accoutrements; but the largest establishment is the manufactory of tobacco, which, being a royal monopoly, can be sold only by the crown, either in the form of snuff, or in cigars or smaller particles for smoking.

The manufactures of this city are not great in proportion to the whole number of the population. But a large proportion of the inhabitants are ecclesiastics; and a much larger portion are paupers, who have no inducement to work, because they can obtain bare necessaries by going the rounds of different convents, where food is gratuitously bestowed on them, or by receiving from the episcopal palace a share of the alms which are daily dispensed. There are, however, fifteen hundred looms employed in making silk goods of various descriptions. Very little silk is raised in the vicinity of the city, it being principally drawn from Valencia and Murcia, where mulberry-trees abound. There are some manufactories of cloths, serges, hats, stockings, and other more minute articles. There is a very extensive establishment for currying leather, and every part of the process, from the first currying to the conversion into boots, shoes, saddles, bridles, gloves, and other articles, is carried on upon a large scale. The bark of the cork-trees is used for tanning, which, though not so strong as the common oak-bark, is yet in larger quantities found to be equally efficacious.

The foreign trade of Seville is but small, the harbour of Cadiz being more commodious for large vessels. The principal exports are, oil, goat and kid skins, quicksilver, liquorice, shumac, cork, and olives. The imports are almost wholly made through Cadiz.

The streets of Seville are in general so narrow as to forbid the passage of carriages through most of them; and some, in which frequently the best houses are to be found, are so close, that a person standing in the middle and extending both arms may touch the walls on the opposite sides. There is, however, what compensates for this, a fine public walk on the banks of the Guadalquivir, where all that is fashionable of the city may be seen enjoying the cool of the evening. This city was the birthplace of the Emperors Trajan, Adrian, and Theodosius; of Juan de la Cueva, of Diego Velasquez de Silva, and of Francis de Herrara. It is situated in long. 5. 18. W. and lat. 37. 24. N.

SEVRES, Deux, a department of France, formed out of the ancient province of the Lower Poitou. It extends from 1. 37. east, to 0. 8. west longitude, and from 46. 0. to 47. 12. north latitude. It is bounded on the north by the department of the Maine and Loire, on the east by that of Vienne, on the south by the Charente, on the south-west by the Lower Charente, and on the west by Vendée. It comprehends 2135⅕ square miles, or 607,350 hectares, equal to 1,366,538 English acres. In 1834, of this land, 369,297 hectares were under the plough, 18,896 were vineyards, 7280 gardens, 17,466 moors, heaths, pasture, &c., 29,806 woods, and the remainder the sites of towns, rivers, morasses, and uncultivated lands. It is divided into four arrondissements, thirty-one cantons, and 356 communes. Its population in 1836 amounted to 304,105. The surface is generally level, except that a chain of hills, the highest point of which does not exceed 450 feet, extends through the department from north-west to south-east. The chief rivers are the two streams from whence the department takes its name. The Sèvres-Nantaise receives the waters of the Louine and the Chambron, and passes into Vendée; and the Sèvres-Niortaise receives the streams Lamdon and Guerande, and becomes navigable at Niort, and then enters Vendée. There are a great number of smaller streams, most of which reach the sea by the Loire. The agriculture is in a backward state, the oxen are used for the plough, and much of the land is in fallow. The greater part of the cultivators are metayers, dividing the produce with the proprietors. The fertility is such that nearly one half the corn grown is supplied to other districts; and much hay and clover are furnished to the departments that are contiguous. The manufacturing industry is almost exclusively confined to providing necessaries for home consumption. The breed of horses is good, and many of them, as well as of a strong breed of asses, and some mules, are articles of commerce. The only mines are of iron, the ore of which is sent into Charente to be manufactured. There are quarries from which excellent millstones are obtained. The department elects two deputies to the legislative chamber. The capital is the city of Niort, with a population in 1836 of 18,197.

SEWAD, an extensive district in Afghanistan, situated about the thirty-fourth degree of north latitude, and partly bounded by the Indus. The country rises to a great elevation, consisting of snow-clad mountains, interspersed with fertile valleys producing all the finest fruits of Europe. It is about seventy miles in length by forty in breadth, and contains twenty-five valleys, each watered by a separate stream. It is principally inhabited by the tribe of the Yusufzies, who, taking advantage of the difficult passes and strong situations abounding in the country, have not only held themselves independent of the Mogul sovereigns, but have made inroads into their territories. They are a brave and independent people, ready to contribute their quota of troops to any plundering expedition, or in defence of the country.

SEWALIC Mountains. This chain of mountains, which reaches a considerable elevation, divides the province of Delhi from Serinagur, in Northern Hindustan. It is through these mountains that the Ganges enters on the plains of Hindustan, at a place called Hurdwar. The hills, which rise with a moderate though unequal slope from the plains, are skirted with deep forests, which abound with valuable timber, and afford shelter to elephants. These, however, seldom exceed seven feet in height, and hence are not considered so valuable as those caught nearer the sea.

SEWAN, a town of Hindustan, province of Bahar, sixty-six miles north-west from Patna. Long. 84. 25. E. Lat. 26. 11. N.

SEWEE, a district in the province of Beloochistan, situated about the thirty-first degree of north latitude, and bounded on the east by a mountainous ridge of hard black rock.

Sewer
||
Sex.

SEWER, in the household, an officer who arranged on the table the dishes of a king or nobleman.

SEWER is also a passage or gutter made to carry water into the sea or a river, and thereby to preserve the land from inundations and other annoyances.

Common SEWERS, in Rome, were executed at a great expense. It was proposed that they should be of sufficient dimensions to admit a waggon loaded with hay. When these common sewers came to be obstructed, or out of repair, under the republic, the censors contracted to pay a thousand talents, or about L.193,000, for clearing and repairing them. They were again in disrepair at the accession of Augustus Cæsar, and the reinstating of them is mentioned among the great works of Agrippa. He is said to have turned the course of seven rivers into these subterraneous passages, to have made them navigable, and to have actually passed in barges under the streets and buildings of Rome. These works are still supposed to remain; but as they exceed the power and resources of the present city to keep them in repair, they are quite concealed, except at one or two places. They were, in the midst of the Roman greatness, and still are, reckoned among the wonders of the world; and yet they are said to have been works of the elder Tarquin, a prince whose territory did not extend in any direction above sixteen miles; and, on this supposition, they must have been made to accommodate a city that was calculated chiefly for the reception of cattle, herdsmen, and banditti. Rude nations sometimes execute works of great magnificence, as fortresses and temples, for the purposes of war and superstition; but seldom palaces, and still more seldom works of mere convenience and cleanliness, in which, for the most part, they are long defective. It is not unreasonable, therefore, to question the authority of tradition in respect to this singular monument of antiquity, which so greatly exceeds what the best accommodated city of modern Europe could undertake for its own convenience. And as those works are still entire, and may continue so for thousands of years, it may be suspected that they were even prior to the settlement of Romulus, and may have been the remains of a more ancient city, on the ruins of which the followers of Romulus settled, as the Arabs now encamp on the ruins of Palmyra and Baalbeck. Livy owns, that the common sewers were not accommodated to the plan of Rome as it was laid out in his time; they were carried in directions across the streets, and passed under buildings of the greatest antiquity. This derangement, indeed, he imputes to the hasty rebuilding of the city after its destruction by the Gauls; but haste, it is probable, would have determined the people to build on their old foundations, or at least not to change them so much as to cross the direction of former streets.

SEWISTAN. See SEISTAN.

SEWURI, an oriental kind of guitar.

SEX, the property by which any animal is male or female. "The primary matter of which women are constituted appears to be more flexible, irritable, and elastic, than that of man. They are formed to maternal mildness and affection; all their organs are tender, yielding, easily wounded, sensible, and receptible."

"The female thinks not profoundly; profound thought is the power of the man. Women feel more. Sensibility is the power of woman. They often rule more effectually, more sovereignly, than man. They rule with tender looks, tears, and sighs, but not with passion and threats."

"Men embrace the whole, women remark individually, and take more delight in selecting the minutiæ which form the whole. Man hears the bursting thunder, views the destructive bolt, with serene aspect, and stands erect amidst the fearful majesty of the streaming clouds. Woman trembles at the lightning, and the voice of distant thunder, and shrinks into herself, or sinks into the arms of man. Man receives a ray of light single; woman delights to view it through a prism in all its dazzling colours."

In determining the comparative merit of the two sexes, it is no derogation from female excellency that it differs in kind from that which distinguishes the male part of our species; and if, in general, it shall be found that women fill up their appointed circle of action with greater regularity than men, the claim of preference cannot justly be decided in our favour. In the prudential and economical parts of life, it is undeniable that they rise far above us; and if true fortitude of mind is best discovered by a cheerful resignation to the measures of Providence, we shall find little reason to claim that exalted virtue as our peculiar privilege. But whatever real difference there may be between the moral or intellectual powers of the male and female mind, nature does not seem to have marked the distinction so strongly as our vanity is willing to imagine; and after all, perhaps, education will be found to occasion the chief distinction.

SEXAGENARY, something relating to the number sixty. Thus sexagenary or sexagesimal arithmetic is a method of computation proceeding by sixties, such as that used in the division of a degree into sixty minutes, of the minute into sixty seconds, and of the second into sixty thirds. Sexagenary tables are also tables of proportional parts, showing the product of two sexagenaries that are to be multiplied, or the quotient of the two that are to be divided.

SEXAGESIMA, the second Sunday before Lent, or the next to Shrove Sunday; so called as being about the sixtieth day before Easter.

SEXAGESIMALS, or *SEXAGESIMAL Fractions*, fractions whose denominators proceed in a sexagecuple ratio; that is, a prime, or the first minute $= \frac{1}{60}$; a second $= \frac{1}{3600}$; a third $= \frac{1}{216000}$. Anciently there were no other than sexagesimals used in astronomy; and they are still retained in many cases, though decimal arithmetic has come into use now in astronomical calculations. In these fractions, which some call *astronomical fractions*, the denominator, being always 60, or a multiple of that number, is usually omitted, and the numerator only written down. Thus 4°, $59'$, $32''$, $50'''$, $16''''$, is to be read, 4 degrees, 59 minutes, 32 seconds, 50 thirds, and 16 fourths.

SEXTANS, SEXTANT, a sixth part of certain things. The Romans having divided their *as* into twelve ounces or uncia, the sixth part of that, or two ounces, was the sextans.

Sextans was also a measure which contained two ounces of liquor, or two cyathi.

SEXTANS, in *Astronomy*, a constellation of the southern hemisphere, made by Hevelius out of unformed stars. In Hevelius's catalogue it contains eleven, but in the British forty-one stars.

SEXTANT, in *Mathematics*, denotes the sixth part of a circle, or an arch comprehending sixty degrees.

The word sextant is more particularly used for an astronomical instrument made like a quadrant, excepting that its limb only comprehends sixty degrees. The use and application of the sextant is the same with that of the quadrant.

SEXTILE, SEXTILIS, the position or aspect of two planets when at sixty degrees distance, or at the distance of two signs from one another. It is marked thus (*).

SEXTIUS, QUINTUS, a Pythagorean philosopher, who flourished in the time of Augustus. He seemed formed to rise in the republic; but he shrunk from civil honours, and declined accepting the rank of senator when it was offered him by Julius Cæsar, that he might have time to apply to philosophy. It appears that he wished to establish a school at Rome, and that his tenets, though chiefly drawn from the doctrines of Pythagoras, in some particulars resembled those of the Stoics.

He soon found himself involved in many difficulties. His laws were tinctured with great severity, and in an early period of this establishment he found his mind so harassed, and the harshness of the doctrines which he wished to establish so repulsive, that he had nearly resolved to put a period to his existence.

Of the school of Sextius were Fabianus, Sotion, Flavianus, Crassitius, and Celsus. Of his works only a few fragments remain; and whether any of them formed a part of the work which Seneca admired so much, cannot now be determined. Some of his maxims are valuable. He recommended an examination of the actions of the day to his scholars when they retired to rest; and he taught, that the road to heaven was by frugality, temperance, and fortitude. He used to recommend holding a looking-glass before persons disordered with passion. He enjoined his scholars to abstain from animal food.

SEXTON, a church-officer, thus called by corruption of the Latin, *sacrista*, or Saxon, *segerstone*, which denotes the same thing. His office is to take care of the vessels, vestments, and other things belonging to the church; and to attend the minister, church-warden, and others at church. He is usually chosen by the parson only. Sextons, as well as parish-clerks, are regarded by the common law as persons who have a freehold in their offices; and, therefore, though they may be punished, yet they cannot be deprived by ecclesiastical censures.

The office of sexton in the pope's chapel is appropriated to the order of the hermits of St Augustin. He is generally a bishop, though sometimes the pope only gives a bishopric *in partibus* to him on whom he confers the post. He takes the title of *Prefect of the Pope's Sacristy*, and has the keeping of the vessels of gold and silver, the relics, and so forth. When the pope says mass, the sexton always tastes the bread and wine first. If it be in private he says mass, his holiness, of two wafers, gives him one to eat; and if in public, the cardinal, who assists the pope in quality of deacon, of three wafers, gives him one to eat. When the pope is desperately sick, he administers to him the sacrament of extreme unction, and enters the conclave in quality of first conclavist.

The office of sexton in Sweden is sometimes singular. During M. Outhier's stay at Stockholm in 1736, he visited the church of St Clara, and during divine service he observed a sexton going about with a long rod, waking those persons who had fallen asleep.

SEXTUPLE, in *Music*, denotes a mixed sort of triple, which is beaten in double time.

SEXTUS Empiricus, a famous Pyrrhonian philosopher, who lived in the second century, under the reign of Antoninus. He was a physician of the sect of the Empirics, and is said to have been one of the preceptors of Antoninus the Philosopher. There are still extant his Pyrrhonian Institutions, and a large work against the mathematicians. The best edition of Sextus Empiricus is that of Fabricius in Greek and Latin, printed at Leipsic in 1718, folio.

SEXUALISTÆ, among botanical writers, those who have established the classes of plants upon the differences of the sexes and parts of fructification in plants, according to the modern method.

SEYNE, La, a city of France, in the department of the Var, and the arrondissement of Toulon. It is a port on a small bay or roadstead, about three miles from Toulon. It is well built, has good quays, and an establishment for building vessels. It contains 5230 inhabitants, many of whom are occupied in fishing for sardinias and tunnies.

SEYSUMAH, a town of the Mahratta territories, in Hindustan, province of Malwah, situated on the east side of the Chumbul. It is twenty miles south-west from Kotah. Long. 75. 37. E. Lat. 24. 55. N.

SEZAWUL, a Hindu word, used in Bengal to express an officer employed at a monthly salary to collect the revenue.

SHACK, in ancient customs, a liberty of winter-pasturage. In the counties of Norfolk and Suffolk, the lord of the manor has shack, that is, a liberty of feeding his sheep at pleasure in his tenants' lands during the six winter months. In Norfolk, shack also extends to the common for hogs, in all men's grounds, from the end of harvest till seed-time. Hence to go *a-shack* is to feed at large.

SHACKLES, aboard a ship, are those oblong iron rings, bigger at one end than at the other, with which the ports are shut fast, by thrusting the wooden bar of the port through them. There is also a sort of shackles to lift up the hatches with, of a like figure, but smaller. They are fastened at the corners of the hatches.

SHADOW, in *Optics*, a privation or diminution of light, by the interposition of an opaque body; or a plane where the light is either altogether obstructed, or greatly weakened, by the interposition of some opaque body between it and the luminary.

Shadow, in *Perspective*. The appearance of an opaque body, and a luminous one whose rays diverge, being given; to find the just appearance of the shadow, according to the laws of perspective. The method is this. From the luminous body, which is here considered as a point, let fall a perpendicular to the perspective plane or table, that is, find the appearance of a point upon which a perpendicular, drawn from the middle of the luminary, falls on the perspective plane; and from the several angles, or raised points of the body, let fall perpendiculars to the plane. These points, on which the perpendiculars fall, connect by right lines with the point upon which the perpendicular let fall from the luminary falls, and continue the lines to the side opposite to the luminary. Lastly, through the raised points draw lines through the centre of the luminary, intersecting the former; the points of intersection are the terms or bounds of the shadow.

SHADOWRAH, a town of Hindustan, in the Mahratta territories, province of Malwah, forty miles north by west from Seronge. Long. 77. 47. E. Lat. 24. 20. N.

SHADWEL, Thomas, descended of an ancient family in Staffordshire, was born in 1640, and educated at Caius College, Cambridge. He was then placed in the Middle Temple to study the laws; and having spent some time there, he travelled abroad. Upon his return home, he became acquainted with the most celebrated persons of wit in that age. He applied himself chiefly to dramatic writing, in which he had great success, and upon the Revolution was made poet laureat and historiographer to King William and Queen Mary, in the room of Mr Dryden. These employments he enjoyed till his death, which happened in 1692. Besides his dramatic writings, he composed several other pieces of poetry, the chief of which are his congratulatory poem on the Prince of Orange's coming to England, another on Queen Mary, and his translation of Juvenal's tenth satire. Mr Dryden treats him with great contempt, in his satire called *Macflecno*. The best judges of that age, however, gave their testimony in favour of his comedies, which have in them fine strokes of humour; the characters are often original, strongly marked, and well sustained. An edition of his works, with some account of his life and writings prefixed, was published in 1720, in four vols. 8vo.

SHADWELL, a large village of the county of Middlesex, in the hundred of Ossulston, touching on the city of London, but lower down on the same bank of the Thames, two miles and a half from St Paul's church. It is within the bills of mortality, and is a parish of itself. The population consists chiefly of sea-faring people, and of such as are connected with the building and equipment of shipping. The parish church is a large and handsome building, dedicated to St Paul. The inhabitants amounted in 1821 to 9557, and in 1831 to 9544. Many of the smaller houses, more than two hundred, have been taken down to make space for the docks that have been built, which accounts for the decrease in the population.

SHAFRAS, or Suffras, Gregory Savarof, an Armenian merchant, remarkable only as the person who sold the large and celebrated diamond which is now set in the imperial sceptre of Russia. Shah Nadir, an Indian prince, had two principal diamonds in his throne, one of them denominated the Sun of the Sea, and the other the Moon of the Mountain. When that prince was assassinated, many precious ornaments belonging to the crown were pillaged, and privately disposed of by the soldiers who shared the plunder.

Shafras, who was called *Millionshik* at Astrakhan, had then his residence at Bassora, with two of his brothers. A chief of the Afghans one day applied to him, and proposed to sell the diamond already mentioned for a very moderate sum (probably the Moon of the Mountain), together with a very large emerald, a ruby of considerable size, and other precious stones of less value. Shafras was astonished at the offer; and giving out that he had not a sufficient sum to purchase them, he requested time to consult with his brothers on the subject. The vender did not again make his appearance, probably from suspicious motives. Shafras, with the approbation of his brothers, went directly in search of the stranger with the jewels, but by that time he had left Bassora. Shafras, however, accidentally met him at Bagdad, and paid him 50,000 piastres (L.8958. 6s. 8d.) for all his jewels. Shafras and his brothers, being well aware that the most profound secrecy was absolutely necessary, resolved to remain at Bassora.

At the expiration of twelve years, Shafras set off with the largest of the jewels, directing his route through Sham and Constantinople, and afterwards through Hungary and Silesia to the city of Amsterdam by land, where he publicly offered them for sale.

It is reported that the British government was among the bidders. The Russian court sent for the large diamond, with an offer to reimburse all reasonable expenses if the price could not be agreed on. When the diamond arrived, Count Panin, the Russian minister, made the following offer to Shafras. Besides the patent of hereditary nobility, which the vender demanded, he was to receive an annual pension of 6000 roubles during life, 500,000 roubles in cash (L.112,500 sterling), one fifth of which was to be payable on demand, and the remainder by instalments in the course of ten years. He also claimed the order of nobility for his brothers, persisting so obstinately in his demands, that the diamond was returned.

Shafras was now very much perplexed. He had involved himself in expenses, was forced to pay interest for considerable sums of borrowed money, and he saw no prospect of selling the jewel to advantage. The negociation was recommenced with Russia by Count Gregory Grigorevitsh Orlof, afterwards created a prince of the empire; and the diamond was purchased for 450,000 roubles (L.105,250) ready money, together with a grant of Russian nobility. We are informed that 120,000 roubles (L.27,000) fell to the share of the negociators for commission, interest, and similar expenses. Shafras settled at Astrakhan; and his riches, which by inheritance devolved to his daughters, have been in a great measure dissipated by the extravagance of his sons-in-law.

SHAFTESBURY, a town in the hundred of Rudland, in the county of Dorset, 101 miles from London. It stands on a hill, is not well supplied with water, and the houses are generally of an humble character. It contains three parishes, with their respective churches. It is an ancient town, supposed to have been founded by Alfred. It is a borough, with a mayor, recorder, and twelve burgesses, and returned two members to parliament till 1832, but now elects only one. The chief trade is making shirt-buttons. The population in 1821 amounted to 2903, and in 1831 to 3061.

SHAGREEN, or Chagreen, in *Commerce*, a kind of grained leather prepared of the skin of a species of squalus, and much used in covering cases, books, and other articles. The best is that which is brought from Constantinople, and is of a brownish colour; the white is the worst. It is extremely hard, yet, when steeped in water, it becomes very soft and pliable; and hence it is of great use among case-makers. It takes any colour that is given to it, red, green, yellow, or black. It is frequently counterfeited, by using morocco formed like shagreen; but this last is distinguished by its peeling off, which the first does not.

SHAHABAD, an extensive town and district of Hindustan, province of Bahar, most advantageously situated between the rivers Soane and Ganges. It is fertile and tolerably well cultivated, and produces barley, wheat, tobacco, and some pease of a small kind. It is estimated to contain more than a million of inhabitants, in the proportion of nineteen Hindus to one Mahommedan. Its chief towns are Chunar, Boujepore, and Arrah. The town is situated on the east side of the Gurrah river, in the district of Khyrabad. It was formerly a large place, but has now fallen greatly to decay. Long. 79. 55 E. Lat. 27. 39. N. There is another town of this name, in the province of Delhi, belonging to the Sikhs, which has also fallen into decay. It is 105 miles north by west from Delhi. Long. 76. 28. E. Lat. 30. 12. N.

SHAHJEHANPOOR, a considerable town of Hindustan, in the Mahratta territories, province of Malwah, situated on the banks of the Sagormutty river, forty miles north-north-east from Oojain. Long. 76. 18. E. Lat. 23. 28. N. There is another town of the same name, in the province of Delhi, district of Bareilly, situated on the Gurrah river, ninety-five miles north-east from Lucknow. Long. 79. 53. E. Lat. 27. 51. N. Both these towns are called after Shah Jehan, who reigned in the middle of the seventeenth century.

SHAHNOOR, Sanore, Sevanore, or Savanoor, a town of Hindustan, in the province of Bejapoor, fifty miles south-south-east from Darwar, and capital of a district of the same name. It was formerly a fortified town, and contained a palace and many good buildings, the greater part of which are now in ruins. It is a place of no strength, though it is enclosed by a wall and ditch. Outside the wall to the northward are several long streets of houses, mostly uninhabited. This place was conquered from the Hindus by the Bhamenee sovereigns in 1397; it afterwards became the capital of a small Patan state, its hereditary possessor receiving the title of nabob. Abdul Hakeem Khan, the seventh lineal descendant, reigned in 1792, and was tributary to Tippoo till 1784, when he accepted the protection of the Mahrattas, on which his territories were ravaged by the armies of Tippoo, the palaces and public buildings were destroyed and razed, and the whole country was laid waste. In 1792 it was wrested from him and restored to the nabob. The district is now under the peishwa's government, being part of the territory received in exchange from the British government for an equivalent in Bundelcund. Long. 75. 22. E. Lat. 15. 1. N.

SHAHPOOR, a town of Hindustan, in the province of Berar, in the Nagpoor rajah's territories, seventy miles north by west from Ellichpoor. Long. 78. 23. E. Lat. 22. 19. N. There is another Shahpoor in the province of Berar, sixty-five miles north-east from Jalnapoor. Long. 78. 1. E. Lat. 19. 49. N. Also one in the Sikh territories, province of Lahore, situated on the east side of the Ravey river, sixty miles north-east from the city of Lahore. Long. 74. 45. E. Lat. 32. 19. N. There are various other towns in Hindustan of this name, which signifies King's Town, many of them of too little consequence to merit any particular notice.

SHAIRGHUR, a town of Hindustan, in the province of Delhi, twenty-six miles north from Bareilly. Long. 79. 21. E. Lat. 28. 40. N.

SHAKSPEARE.[1]

Shakspeare.

William Shakspeare, the protagonist on the great arena of modern poetry, and the glory of the human intellect, was born at Stratford-upon-Avon, in the county of Warwick, in the year 1564, and upon some day, not precisely ascertained, in the month of April. It is certain that he was baptized on the 25th; and from that fact, combined with some shadow of a tradition, Malone has inferred that he was born on the 23d. There is doubtless, on the one hand, no absolute necessity deducible from law or custom, as either operated in those times, which obliges us to adopt such a conclusion; for children might be baptized, and were baptized. at various distances from their birth: yet, on the other hand, the 23d is as likely to have been the day as any other; and more likely than any earlier day, upon two arguments. First, because there was probably a tradition floating in the seventeenth century, that Shakspeare died upon his birth-day: now it is beyond a doubt that he died upon the 23d of April. Secondly, because it is a reasonable presumption, that no parents, living in a simple community, tenderly alive to the pieties of household duty, and in an age still clinging reverentially to the ceremonial ordinances of religion, would much delay the adoption of their child into the great family of Christ. Considering the extreme frailty of an infant's life during its two earliest years, to delay would often be to disinherit the child of its Christian privileges; privileges not the less eloquent to the feelings from being profoundly mysterious, and, in the English church, forced not only upon the attention, but even upon the eye, of the most thoughtless. According to the discipline of the English church, the unbaptized are buried with "maimed rites," shorn of their obsequies, and sternly denied that "sweet and solemn farewell" by which otherwise the church expresses her final charity with all men; and not only so, but they are even *locally* separated and sequestrated. Ground the most hallowed, and populous with Christian burials of households,

> That died in peace with one another,
> Father, sister, son, and brother.

opens to receive the vilest malefactor; by which the church symbolically expresses her maternal willingness to gather back into her fold those even of her flock who have strayed from her by the most memorable aberrations; and yet, with all this indulgence, she banishes to unhallowed ground the innocent bodies of the unbaptized. To them and to suicides she turns a face of wrath. With this gloomy fact offered to the very external senses, it is difficult to suppose that any parents would risk their own reproaches by putting the fulfilment of so grave a duty on the hazard of a convulsion fit. The case of royal children is different; their baptisms, it is true, were often delayed for weeks; but the household chaplains of the palace were always at hand, night and day, to baptize them in the very agonies of death.[2] We must presume, therefore, that William Shakspeare was born on some day very little anterior to that of his baptism; and the more so because the season of the year was lovely and genial, the 23d of April in 1564 corresponding in fact with what we now call the 3d of May, so that, whether the child was to be carried abroad, or the clergyman to be summoned, no hindrance would arise from the weather. One only argument has sometimes struck us for supposing that the 22d might be the day, and not the 23d; which is, that Shakspeare's sole grand-daughter, Lady Barnard, was married on the 22d of April 1626, ten years exactly from the poet's death; and the reason for choosing this day *might* have had a reference to her illustrious grandfather's birthday; which, there is good reason for thinking, would be celebrated as a festival in the family for generations. Still this choice *may* have been an accident, or governed merely by reason of convenience. And, on the whole, it is as well perhaps to acquiesce in the old belief, that Shakspeare was born and died on the 23d of April. We cannot do wrong if we drink to his memory on both 22d and 23d.

On a first review of the circumstances, we have reason to feel no little perplexity in finding the materials for a life of this transcendent writer so meagre and so few; and amongst them the larger part of doubtful authority. All the energy of curiosity directed upon this subject, through a period of one hundred and fifty years (for so long it is since Betterton the actor began to make researches) has availed us little or nothing. Neither the local traditions of his provincial birth-place, though sharing with London through half a century the honour of his familiar presence, nor the recollections of that brilliant literary circle with whom he lived in the metropolis, have yielded much more than such an outline of his history as is oftentimes to be gathered from the penurious records of a grave-stone. That he lived, and that he died, and that he was "a little lower than the angels;"—these make up pretty nearly the amount of our undisputed report. It may be doubted indeed whether at this day we are as accurately acquainted with the life of Shakspeare as with that of Chaucer, though divided from each other by an interval of two centuries, and (what should have been more effectual towards oblivion) by the wars of the two roses. And yet the traditional memory of a rural and a sylvan region, such as Warwickshire at that time was, is usually exact as well as tenacious; and, with respect to Shakspeare in particular, we may presume it to have been full and circumstantial through the generation succeeding to his own, not only from the curiosity, and perhaps something of a scandalous interest, which would pursue the motions of one living so large a part of his life at a distance from his wife, but also from the final reverence and honour which would settle upon the memory of a poet so pre-eminently successful; of one who, in a space of five-and-twenty years, after running a bright career in the capital city of his native land, and challenging notice from the throne, had retired with an ample fortune, created by his personal efforts, and by labours purely intellectual.

---

[1] Mr Campbell, the latest editor of Shakspeare's dramatic works, observes that "the poet's name has been variously written Shaxpeare, Shackspeare, Shakspeare, and Shakspere;" to which varieties might be added Shagspere, from the Worcester Marriage License, published in 1836. But the fact is, that by combining with all the differences in spelling the first syllable, all those in spelling the second, more than twenty-five distinct varieties of the name may be expanded (like an algebraic series), for the choice of the curious in mis-spelling. Above all things, those varieties which arise from the intercalation of the middle *e* (that is, the *e* immediately before the final syllable *spear*), can never be overlooked by those who remember, at the opening of the Dunciad, the note upon this very question about the orthography of Shakspeare's name, as also upon the other great question about the title of the immortal Satire, Whether it ought not to have been the Dunceiade, seeing that Dunce, its great author and progenitor, cannot possibly dispense with the letter *e*. Meantime we must remark, that the first three of Mr Campbell's variations are mere caprices of the press; as is Shagspere; or, more probably, this last euphonious variety arose out of the gross clownish pronunciation of the two hiccuping "*marksmen*" who rode over to Worcester for the license; and one cannot forbear laughing at the bishop's secretary for having been so misled by two varlets, professedly incapable of signing their own names. The same drunken villains had cut down the bride's name *Hathaway* into *Hathwey*. Finally, to treat the matter with seriousness, Sir Frederick Madden has shown, in his recent letter to the Society of Antiquaries, that the poet himself in all probability wrote the name uniformly *Shakspere*. Orthography, both of proper names, of appellatives, and of words universally, was very unsettled up to a period long subsequent to that of Shakspeare. Still it must usually have happened that names written variously and laxly by others, would be written uniformly by the owners; especially by those owners who had occasion to sign their names frequently, and by literary people, whose attention was often, as well as consciously, directed to the proprieties of spelling. *Shakspeare* is now too familiar to the eye for any alteration to be attempted; but it is pretty certain that Sir Frederick Madden is right in stating the poet's own signature to have been uniformly *Shakspere*. It is so written twice in the course of his will, and it is so written on a blank leaf of Florio's English translation of Montaigne's Essays; a book recently discovered, and sold, on account of its autograph, for a hundred guineas.

[2] But, as a proof that, even in the case of royal christenings, it was not thought pious to "tempt God," as it were, by delay, Edward VI. the only son of Henry VIII. was born on the 12th day of October in the year 1537. And there was a delay on account of the sponsors, since the birth was not in London. Yet how little that delay was made, may be seen by this fact: The birth took place in the dead of the night, the day was Friday; and yet, in spite of all delay, the christening was most pompously celebrated on the succeeding Monday. And Prince Arthur, the elder brother of Henry VIII. was christened on the very next Sunday succeeding to his birth, notwithstanding an inevitable delay, occasioned by the distance of Lord Oxford, his godfather, and the excessive rains, which prevented the earl being reached by couriers, or himself reaching Winchester, without extraordinary exertions.

How are we to account, then, for that deluge, as if from Lethe, which has swept away so entirely the traditional memorials of one so illustrious? Such is the fatality of error which overclouds every question connected with Shakspeare, that two of his principal critics, Steevens and Malone, have endeavoured to solve the difficulty by cutting it with a falsehood. They deny in effect that he *was* illustrious in the century succeeding to his own, however much he has since become so. We shall first produce their statements in their own words, and we shall then briefly review them.

Steevens delivers *his* opinion in the following terms:—"How little Shakspeare was once read, may be understood from Tate, who, in his dedication to the altered play of King Lear, speaks of the original as an obscure piece, recommended to his notice by a friend; and the author of the Tatler, having occasion to quote a few lines out of Macbeth, was content to receive them from Davenant's alteration of that celebrated drama, in which almost every original beauty is either awkwardly disguised or arbitrarily omitted." Another critic, who cites this passage from Steevens, pursues the hypothesis as follows:—"In fifty years after his death, Dryden mentions that he was then become *a little obsolete.* In the beginning of the last century, Lord Shaftesbury complains of his *rude unpolished style, and his antiquated phrase and wit.* It is certain that, for nearly a hundred years after his death, partly owing to the immediate revolution and rebellion, and partly to the licentious taste encouraged in Charles II.'s time, and perhaps partly to the incorrect state of his works, he was ALMOST ENTIRELY NEGLECTED." This critic then goes on to quote with approbation the opinion of Malone,—"that if he had been read, admired, studied, and imitated, in the same degree as he is now, the enthusiasm of some one or other of his admirers in the last age would have induced him to make some inquiries concerning the history of his theatrical career, and the anecdotes of his private life." After which this enlightened writer re-affirms and clenches the judgment he has quoted by saying,—"His admirers, however, *if he had admirers in that age,* possessed no portion of such enthusiasm."

It may perhaps be an instructive lesson to young readers, if we now show them, by a short sifting of these confident dogmatists, how easy it is for a careless or a half-read man to circulate the most absolute falsehoods under the semblance of truth; falsehoods which impose upon himself as much as they do upon others. We believe that not one word or illustration is uttered in the sentences cited from these three critics, which is not *virtually* in the very teeth of the truth.

To begin with Mr Nahum Tate:—This poor grub of literature, if he did really speak of Lear as "an *obscure* piece, recommended to his notice by a friend," of which we must be allowed to doubt, was then uttering a conscious falsehood. It happens that Lear was one of the few Shakspearian dramas which had kept the stage unaltered. But it is easy to see a mercenary motive in such an artifice as this. Mr Nahum Tate is not of a class of whom it can be safe to say that they are "well known:" they and their desperate tricks are essentially obscure, and good reason he has to exult in the felicity of such obscurity; for else this same vilest of travesties, Mr Nahum's Lear, would consecrate his name to everlasting scorn. For himself, he belonged to the age of Dryden rather than of Pope: he "flourished," if we can use such a phrase of one who was always withering, about the era of the Revolution; and his Lear, we believe, was arranged in the year 1682. But the family to which he belongs is abundantly recorded in the Dunciad; and his own name will be found amongst its catalogues of heroes.

With respect to *the author of the Tatler*, a very different explanation is requisite. Steevens means the reader to understand Addison; but it does not follow that the particular paper in question was from his pen. Nothing, however, could be more natural than to quote from the common form of the play as then in possession of the stage. It was *there*, beyond a doubt, that a fine gentleman living upon town, and not professing any deep scholastic knowledge of literature (a light in which we are always to regard the writers of the Spectator, Guardian, &c.), would be likely to have learned anything he quoted from Macbeth. This we say generally of the writers in those periodical papers; but, with reference to Addison in particular, it is time to correct the popular notion of his literary character, or at least to mark it by severer lines of distinction. It is already pretty well known, that Addison had no very intimate acquaintance with the literature of his own country. It is known also, that he did not think such an acquaintance any ways essential to the character of an elegant scholar and *littérateur*. Quite enough he found it, and more than enough for the time he had to spare, if he could maintain a tolerable familiarity with the foremost Latin poets, and a very slender one indeed with the Grecian. *How* slender, we can see in his "Travels." Of modern authors, none as yet had been published with notes, commentaries, or critical collations of the text; and, accordingly, Addison looked upon all of them, except those few who professed themselves followers in the retinue and equipage of the ancients, as creatures of a lower race. Boileau, as a mere imitator and propagator of Horace, he read, and probably little else, amongst the French classics. Hence it arose that he took upon himself to speak sneeringly of Tasso. To this, which was a bold act for his timid mind, he was emboldened by the countenance of Boileau. Of the elder Italian authors, such as Ariosto, and, *a fortiori*, Dante, he knew absolutely nothing. Passing to our own literature, it is certain that Addison was profoundly ignorant of Chaucer and of Spenser. Milton only,—and why? simply because he was a brilliant scholar, and stands like a bridge between the Christian literature and the Pagan,—Addison had read and esteemed. There was also in the very constitution of Milton's mind, in the majestic regularity and planetary solemnity of its *epic* movements, something which he could understand and appreciate: as to the meteoric and incalculable eccentricities of the *dramatic* mind, as it displayed itself in the heroic age of our drama, amongst the Titans of 1590–1630, they confounded and overwhelmed him.

In particular, with regard to Shakspeare, we shall now proclaim a discovery which we made some twenty years ago. We, like others, from seeing frequent references to Shakspeare in the Spectator, had acquiesced in the common belief, that, although Addison was no doubt profoundly unlearned in Shakspeare's language, and thoroughly unable to do him justice (and this we might well assume, since his great rival Pope, who had expressly studied Shakspeare, was, after all, so memorably deficient in the appropriate knowledge),—yet, that of course he had a vague popular knowledge of the mighty poet's cardinal dramas. Accident only led us into a discovery of our mistake. Twice or thrice we had observed, that if Shakspeare were quoted, that paper turned out not to be Addison's; and at length, by express examination, we ascertained the curious fact, that Addison has never in one instance quoted or made any reference to Shakspeare. But was this, as Steevens most disingenuously pretends, to be taken as an exponent of the public feeling towards Shakspeare? Was Addison's neglect representative of a general neglect? If so, whence came Rowe's edition, Pope's, Theobald's, Sir Thomas Hanmer's, Bishop Warburton's, all upon the heels of one another? With such facts staring him in the face, how shameless must be that critic who could, in support of such a thesis, refer to "*the author of the Tatler*," contemporary with all these editors. The truth is, Addison was well aware of Shakspeare's hold on the popular mind; too well aware of it. The feeble constitution of the poetic faculty, as existing in himself, forbade his sympathising with Shakspeare; the proportions were too colossal for his delicate vision; and yet, as one who sought popularity himself, he durst not shock what perhaps he viewed as a national prejudice. Those who have happened, like ourselves, to see the effect of passionate music and "deep-inwoven harmonics" upon the feeling of an idiot,[1] may conceive what we mean. Such music does not utterly revolt the idiot; on the contrary, it has a strange but a horrid fascination for him: it alarms, irritates, disturbs, makes him profoundly unhappy; and chiefly by unlocking imperfect glimpses of thoughts and slumbering instincts, which it is for his peace to have entirely obscured, because for him they can be revealed only partially, and with the sad effect of throwing a baleful gleam upon his blighted condition. Do we mean, then, to compare Addison with an idiot? Not generally, by any means. Nobody can more sincerely admire him where he was a man of real genius, viz. in his delineations of character and manners, or in the exquisite delicacies of his humour. But assuredly Addison, as a poet, was amongst the sons of the feeble; and between the authors of Cato and of King Lear there was a gulf never to be bridged over.[2]

But Dryden, we are told, pronounced Shakspeare already in *his* day "*a little obsolete*." Here now we have wilful, deliberate falsehood. *Obsolete*, in Dryden's meaning, does not imply that he was so with regard to his popularity (the question then at issue), but with regard to his diction and choice of words. To cite Dryden as a witness for any purpose against Shakspeare,—Dryden, who of all men had the most ransacked wit and exhausted language in celebrating the supremacy of Shakspeare's genius, does indeed require as much shamelessness in feeling as mendacity in principle.

But then Lord Shaftesbury, who may be taken as half way between Dryden and Pope (Dryden died in 1700, Pope was then twelve years old, and Lord S. wrote chiefly, we believe, between 1700 and 1710), "complains," it seems, "of his rude unpolished style, and his antiquated phrase and wit." What if he does? Let the whole truth be told, and then we shall see how much stress is to be laid upon such a judgment. The second Lord Shaftesbury, the author of the Characteristics, was the grandson of that famous political agitator, the Chancellor Shaftesbury, who passed his whole life in storms of his own creation. The second Lord Shaftesbury was a man of crazy constitution, querulous from ill health, and had received an eccentric education from his eccentric grandfather. He was practised daily in *talking* Latin, to which afterwards he added a competent study of the Greek; and finally he became unusually learned for his rank, but the most absolute and undistinguishing pedant that perhaps literature has to show. He sneers continually at the regular-built academic pedant; but he himself, though no academic, was essentially the very impersonation of pedantry. No thought however beautiful, no image however magnificent, could conciliate his praise as long as it was clothed in English; but present him with the most trivial common-places in Greek, and he unaffectedly fancied them divine; mistaking the pleasurable sense of his own power in a difficult and rare accomplishment for some peculiar force or beauty in the passage. Such was the outline of his literary taste. And was it upon Shakspeare only, or upon him chiefly, that he lavished his pedantry? Far from it. He attacked Milton with no less fervour; he attacked Dryden with a thousand times more. Jeremy Taylor he quoted only to ridicule; and even Locke, the confidential friend of his grandfather, he never alludes to without a sneer. As to Shakspeare, so far from Lord Shaftesbury's censures arguing his deficient reputation, the very fact of his noticing him at all proves his enormous popularity; for upon system he noticed those only who ruled the public taste. The insipidity of his objections to Shakspeare may be judged from this, that he comments in a spirit of absolute puerility upon the name *Desdemona*, as though intentionally formed from the Greek word for *superstition*. In fact, he had evidently read little beyond the list of names in Shakspeare; yet there is proof enough that the irresistible beauty of what little he *had* read was too much for all his pedantry, and startled him exceedingly; for ever afterwards he speaks of Shakspeare as one who, with a little aid from Grecian sources, really had something great and promising about him. As to modern authors, neither this Lord Shaftesbury nor Addison read anything for the latter years of their life but Bayle's Dictionary. And most of the little scintillations of erudition which may be found in the notes to the Characteristics, and in the Essays of Addison, are derived, almost without exception, and uniformly without acknowledgment, from Bayle.[3]

very common failing

Finally, with regard to the sweeping assertion, that "for nearly a hundred years after his death Shakspeare was almost entirely neglected," we shall meet this scandalous falsehood by a rapid view of his fortunes during the century in question. The tradition has always been, that Shakspeare was honoured by the especial notice of Queen Elizabeth, as well as by that of James I. At one time we were disposed to question the truth of this tradition; but that was for want of having read attentively the lines of Ben Jonson to the memory of Shakspeare, those generous lines which have so absurdly been taxed with faint praise. Jonson could make no mistake on this point: he, as one of Shakspeare's familiar companions, must have witnessed at the very time, and accompanied with friendly sympathy, every motion of royal favour towards Shakspeare. Now he, in words which leave no room for doubt, exclaims

---

[1] A great modern poet refers to this very case of music entering "the mouldy chambers of the dull idiot's brain;" but in support of what seems to us a baseless hypothesis.

[2] Probably Addison's fear of the national feeling was a good deal strengthened by his awe of Milton and of Dryden, both of whom had expressed a homage towards Shakspeare which language cannot transcend. Amongst his political friends also were many intense admirers of Shakspeare.

[3] He who is weak enough to kick and spurn his own native literature, even if it were done with more knowledge than is shown by Lord Shaftesbury, will usually be kicked and spurned in his turn; and accordingly it has been often remarked, that the Characteristics are unjustly neglected in our days. For Lord Shaftesbury, with all his pedantry, was a man of great talents. Leibnitz had the sagacity to see this through the mists of a translation.

> Sweet swan of Avon, what a sight it were
> To see thee in our waters yet appear;
> And make those flights upon the banks of Thames
> *That so did take Eliza and our James.*

These princes, then, *were* taken, were fascinated, with some of Shakspeare's dramas. In Elizabeth the approbation would probably be sincere. In James we can readily suppose it to have been assumed; for he was a pedant in a different sense from Lord Shaftesbury; not from undervaluing modern poetry, but from caring little or nothing for any poetry, although he wrote about its mechanic rules. Still the royal *imprimatur* would be influential and serviceable no less when offered hypocritically than in full sincerity. Next let us consider, at the very moment of Shakspeare's death, who were the leaders of the British youth, the *principes juventutis*, in the two fields, equally important to a great poet's fame, of rank and of genius? The Prince of Wales and John Milton; the first being then about sixteen years old, the other about eight. Now these two great powers, as we may call them, these presiding stars over all that was English in thought and action, were both impassioned admirers of Shakspeare. Each of them counts for many thousands. The Prince of Wales[1] had learned to appreciate Shakspeare, not originally from reading him, but from witnessing the court representations of his plays at Whitehall. Afterwards we know that he made Shakspeare his closet companion, for he was reproached with doing so by Milton. And we know also, from the just criticism pronounced upon the character and diction of Caliban by one of Charles's confidential counsellors, Lord Falkland, that the king's admiration of Shakspeare had impressed a determination upon the court reading. As to Milton, by double prejudices, puritanical and classical, his mind had been preoccupied against the full impressions of Shakspeare. And we know that there is such a thing as keeping the sympathies of love and admiration in a dormant state, or state of abeyance; an effort of self-conquest realized in more cases than one by the ancient fathers, both Greek and Latin, with regard to the profane classics. Intellectually they admired, and would not belie their admiration; but they did not give their hearts cordially, they did not abandon themselves to their natural impulses. They averted their eyes and weaned their attention from the dazzling object. Such, probably, was Milton's state of feeling towards Shakspeare after 1642, when the theatres were suppressed, and the fanatical fervour in its noontide heat. Yet even then he did not belie his reverence intellectually for Shakspeare; and in his younger days we know that he had spoken more enthusiastically of Shakspeare than he ever did again of any uninspired author. Not only did he address a sonnet to his memory, in which he declares that kings would wish to die, if by dying they could obtain such a monument in the hearts of men; but he also speaks of him in his *Il Penseroso* as the tutelary genius of the English stage. In this transmission of the torch (λαμπαδοφορια) Dryden succeeds to Milton; he was born nearly thirty years later; about thirty years they were contemporaries; and by thirty years, or nearly, Dryden survived his great leader. Dryden, in fact, lived out the seventeenth century. And we have now arrived within nine years of the era when the critical editions started in hot succession to one another. The names we have mentioned were the great influential names of the century. But of inferior homage there was no end. How came Betterton the actor, how came Davenant, how came Rowe, or Pope, by their intense (if not always sound) admiration for Shakspeare, unless they had found it fuming upwards like incense to the Pagan deities in ancient times from altars erected at every turning upon all the paths of men?

But it is objected that inferior dramatists were sometimes preferred to Shakspeare; and again, that vile travesties of Shakspeare were preferred to the authentic dramas. As to the first argument, let it be remembered, that if the saints of the chapel are always in the same honour, because *there* men are simply discharging a duty, which once due will be due for ever; the saints of the theatre, on the other hand, must bend to the local genius, and to the very reasons for having a theatre at all. Men go thither for amusement: this is the paramount purpose; and even acknowledged merit or absolute superiority must give way to it. Does a man at Paris expect to see Molière reproduced in proportion to his admitted precedency in the French drama? On the contrary, that very precedency argues such a familiarization with his works, that those who are in quest of relaxation will reasonably prefer any recent drama to that which, having lost all its novelty, has lost much of its excitement. We speak of ordinary minds; but in cases of *public* entertainments, deriving part of their power from scenery and stage pomp, novelty is for all minds an essential condition of attraction. Moreover, in some departments of the comic, Beaumont and Fletcher, when writing in combination, really had a freedom and breadth of manner which excels the comedy of Shakspeare. As to the altered Shakspeare as taking precedency of the genuine Shakspeare, no argument can be so frivolous. The public were never allowed a choice; the great majority of an audience even now cannot be expected to carry the real Shakspeare in their mind, so as to pursue a comparison between that and the alteration. Their comparisons must be exclusively amongst what they have opportunities of seeing; that is, between the various pieces presented to them by the managers of theatres. Further than this it is impossible for them to extend their office of judging and collating; and the degenerate taste which substituted the caprices of Davenant, the rants of Dryden, or the filth of Tate, for the jewellery of Shakspeare, cannot with any justice be charged upon the public, not one in a thousand of whom was furnished with any means of comparing, but exclusively upon those (viz. theatrical managers) who had the very amplest. Yet even in excuse for *them* much may be said. The very length of some plays compelled them to make alterations. The best of Shakspeare's dramas, King Lear, is the least fitted for representation; and, even for the vilest alteration, it ought in candour to be considered that possession is nine points of the law. He who would not have introduced, was often obliged to retain.

Finally, it is urged, that the small number of editions through which Shakspeare passed in the seventeenth century, furnishes a separate argument, and a conclusive one, against his popularity. We answer, that, considering the bulk of his plays collectively, the editions were *not* few: compared with any known case, the copies sold of Shakspeare were quite as many as could be expected under the circumstances. Ten or fifteen times as much consideration went to the purchase of one great folio like Shakspeare, as would attend the purchase of a little volume like Waller or Donne. Without reviews, or newspapers, or advertisements to diffuse the knowledge of books, the progress of literature was necessarily slow, and its expansion narrow. But this is a topic which has always been treated unfairly, not with regard to Shakspeare only, but to Milton, as well as many others. The truth is, we have not facts enough to guide us; for the number of editions often tells nothing accurately as to the number of copies. With respect to Shakspeare it is certain, that, had his masterpieces been gathered into small volumes, Shakspeare would have had a most extensive sale. As it was, there can be no doubt, that from his own generation, throughout the seventeenth century, and until the eighteenth began to accommodate, not any greater popularity in *him*, but a greater taste for reading in the public, his fame never ceased to be viewed as a national trophy of honour; and the most illustrious men of the seventeenth century were no whit less fervent in their admiration than those of the eighteenth and the nineteenth, either as respected its strength and sincerity, or as respected its open profession.[1]

---

[1] Perhaps the most bitter political enemy of Charles I. will have the candour to allow that, for a prince of those times, he was truly and eminently accomplished. His knowledge of the arts was considerable; and, as a patron of art, he stands foremost amongst all British sovereigns to this hour. He said truly of himself, and wisely as to the principle, that he understood English law as well as a gentleman ought to understand it; meaning that an attorney's minute knowledge of forms and technical niceties was illiberal. Speaking of him as an author, we must remember that the *Eikon Basiliké* is still unappropriated; that question is still open. But supposing the king's claim negatived, still, in his controversy with Henderson, in his negotiations at the Isle of Wight and elsewhere, he discovered a power of argument, a learning, and a strength of memory, which are truly admirable; whilst the whole of his accomplishments are recommended by a modesty and a humility as rare as they are unaffected.

It is therefore a false notion, that the general sympathy with the merits of Shakspeare ever beat with a languid or intermitting pulse. Undoubtedly, in times when the functions of critical journals and of newspapers were not at hand to diffuse or to strengthen the impressions which emanated from the capital, all opinions must have travelled slowly into the provinces. But even then, whilst the perfect organs of communication were wanting, indirect substitutes were supplied by the necessities of the times, or by the instincts of political zeal. Two channels especially lay open between the great central organ of the national mind, and the remotest provinces. Parliaments were occasionally summoned (for the judges' circuits were too brief to produce much effect); and during their longest suspensions, the nobility, with large retinues, continually resorted to the court. But an intercourse more constant and more comprehensive was maintained through the agency of the two universities. Already, in the time of James I., the growing importance of the gentry, and the consequent birth of a new interest in political questions, had begun to express itself at Oxford, and still more so at Cambridge. Academic persons stationed themselves as sentinels at London, for the purpose of watching the court and the course of public affairs. These persons wrote letters, like those of the celebrated Joseph Mede, which we find in Ellis's Historical Collections, reporting to their fellow-collegians all the novelties of public life as they arose, or personally carried down such reports, and thus conducted the general feelings at the centre into lesser centres, from which again they were diffused into the ten thousand parishes of England; for (with a very few exceptions in favour of poor benefices, Welch or Cumbrian), every parish priest must unavoidably have spent his three years at one or other of the English universities. And by this mode of diffusion it is that we can explain the strength with which Shakspeare's thoughts and diction impressed themselves from a very early period upon the national literature, and even more generally upon the national thinking and conversation.[2]

The question therefore revolves upon us in threefold difficulty, How, having stepped thus prematurely into this inheritance of fame, leaping, as it were, thus abruptly into the favour alike of princes and the enemies of princes, had it become possible that in his native place (honoured still more in the final testimonies of his preference when founding a family mansion), such a man's history, and the personal recollections which cling so affectionately to the great intellectual potentates who have recommended themselves by gracious manners, could so soon and so utterly have been obliterated?

---

[1] The necessity of compression obliges us to omit many arguments and references by which we could demonstrate the fact, that Shakspeare's reputation was always in a progressive state; allowing only for the interruption of about seventeen years, which this poet, in common with all others, sustained, not so much from the state of war (which did not fully occupy four of those years), as from the triumph of a gloomy fanaticism. Deduct the twenty-three years of the seventeenth century which had elapsed before the first folio appeared, to this space add seventeen years of fanatical madness, during fourteen of which *all* dramatic entertainments were suppressed, the remainder is sixty years. And surely the sale of four editions of a vast folio in that space of time was an expression of an abiding interest. *No other poet, except Spenser, continued to sell throughout the century.* Besides, in arguing the case of a *dramatic* poet, we must bear in mind, that although readers of learned books might be diffused over the face of the land, the readers of poetry would be chiefly concentred in the metropolis; and such persons would have no need to buy what they heard at the theatres. But then comes the question, whether Shakspeare kept possession of the theatres. And we are really humiliated by the gross want of sense which has been shown, by Malone chiefly, but also by many others, in discussing this question. From the Restoration to 1682, says Malone, no more than four plays of Shakspeare's were performed by a principal company in London. "Such was the lamentable taste of those times, that the plays of Fletcher, Jonson, and Shirley, were much oftener exhibited than those of our author." What cant is this! If that taste were "lamentable;" what are we to think of our own times, when plays a thousand times below those of Fletcher, or even of Shirley, continually displace Shakspeare? Shakspeare would himself have exulted in finding that he gave way only to dramatists so excellent. And, as we have before observed, both then and now, it is the very familiarity with Shakspeare which often banishes him from audiences honestly in quest of relaxation and amusement. Novelty is the very soul of such relaxation; but in our closets, when we are *not* unbending, when our minds are in a state of tension from intellectual cravings, then it is that we resort to Shakspeare; and oftentimes those who honour him most, like ourselves, are the most impatient of seeing his divine scenes disfigured by unequal representation (good, perhaps, in a single personation, bad in all the rest); or to hear his divine thoughts mangled in the recitation; or (which is worst of all) to hear them dishonoured and defeated by imperfect apprehension in the audience, or by defective sympathy. Meantime, if one theatre played only four of Shakspeare's dramas, another played at least seven. But the grossest folly of Malone is, in fancying the numerous alterations so many insults to Shakspeare, whereas they expressed as much homage to his memory as if the unaltered dramas had been retained. The substance *was* retained. The changes were merely concessions to the changing views of scenical propriety; sometimes, no doubt, made with a simple view to the revolution effected by Davenant at the restoration, in bringing *scenes* (in the painter's sense) upon the stage; sometimes also with a view to the altered fashions of the audience during the suspensions of the action, or perhaps to the introduction of *after-pieces*, by which, of course, the time was abridged for the main performance. A volume might be written upon this subject. Meantime let us never be told, that a poet was losing, or had lost his ground, who found in his lowest depression, amongst his almost idolatrous supporters, a great king distracted by civil wars, a mighty republican poet distracted by puritanical fanaticism, the greatest successor by far of that great poet, a papist and a bigoted royalist, and finally, the leading actor of the century, who gave and reflected the ruling impulses of his age.

[2] One of the profoundest tests by which we can measure the congeniality of an author with the national genius and temper, is the degree in which his thoughts or his phrases interweave themselves with our daily conversation, and pass into the currency of the language. *Few French authors, if any, have imparted one phrase to the colloquial idiom;* with respect to Shakspeare, a large dictionary might be made of such phrases as "win golden opinions," "in my mind's eye," "patience on a monument," "o'erstep the modesty of nature," "more honour'd in the breach than in the observance," "palmy state," "my poverty and not my will consents," and so forth, without end. This reinforcement of the general language, by aids from the mintage of Shakspeare, had already commenced in the seventeenth century.

Malone, with childish irreflection, ascribes the loss of such memorials to the want of enthusiasm in his admirers. Local researches into private history had not then commenced. Such a taste, often petty enough in its management, was the growth of after-ages. Else how came Spenser's life and fortunes to be so utterly overwhelmed in oblivion? No poet of a high order could be more popular.

The answer we believe to be this: Twenty-six years after Shakspeare's death commenced the great parliamentary war: this it was, and the local feuds arising to divide family from family, brother from brother, upon which we must charge the extinction of traditions and memorials, doubtless abundant up to that era. The parliamentary contest, it will be said, did not last above three years; the king's standard having been first raised at Nottingham in August 1642, and the battle of Naseby (which terminated the open warfare) having been fought in June 1645. Or even if we extend its duration to the surrender of the last garrison, that war terminated in the spring of 1646. And the brief explosions of insurrection or of Scottish invasion which occurred on subsequent occasions were all locally confined; and none came near to Warwickshire, except the battle of Worcester, more than five years after. This is true; but a short war will do much to efface recent and merely personal memorials. And the following circumstances of the war were even more important than the general fact.

First of all, the very mansion founded by Shakspeare became the military head-quarters for the queen in 1644, when marching from the eastern coast of England to join the king in Oxford; and one such special visitation would be likely to do more serious mischief in the way of extinction, than many years of general warfare. Secondly, as a fact, perhaps, equally important, Birmingham, the chief town of Warwickshire, and the adjacent district, the seat of our hardware manufactures, was the very focus of disaffection towards the royal cause. Not only, therefore, would this whole region suffer more from internal and spontaneous agitation, but it would be the more frequently traversed vindictively from without, and harassed by flying parties from Oxford, or others of the king's garrisons. Thirdly, even apart from the political aspects of Warwickshire, this county happens to be the central one of England, as regards the roads between the north and south; and Birmingham has long been the great central axis,[1] in which all the radii from the four angles of England proper meet and intersect. Mere accident, therefore, of local position, much more when united with that avowed inveteracy of malignant feeling, which was bitter enough to rouse a re-action of bitterness in the mind of Lord Clarendon, would go far to account for the wreck of many memorials relating to Shakspeare, as well as for the subversion of that quiet and security for humble life, in which the traditional memory finds its best *nidus*. Thus we obtain one solution, and perhaps the main one, of the otherwise mysterious oblivion which had swept away all traces of the mighty poet, by the time when those quiet days revolved upon England, in which again the solitary agent of learned research might roam in security from house to house, gleaning those personal remembrances which, even in the fury of civil strife, might long have lingered by the chimney corner. But the fierce furnace of war had probably, by its *local* ravages, scorched this field of natural tradition, and thinned the gleaner's inheritance by three parts out of four. This, we repeat, may be one part of the solution to this difficult problem.

And if another is still demanded, possibly it may be found in the fact, hostile to the perfect consecration of Shakspeare's memory, that after all he was a player. Many a coarse-minded country gentleman, or village pastor, who would have held his town glorified by the distinction of having sent forth a great judge or an eminent bishop, might disdain to cherish the personal recollections which surrounded one whom custom regarded as little above a mountebank, and the illiberal law as a vagabond. The same degrading appreciation attached both to the actor in plays and to their author. The contemptuous appellation of "play-book," served as readily to degrade the mighty volume which contained Lear and Hamlet, as that of "play-actor," or "player-man," has always served with the illiberal or the fanatical to dishonour the persons of Roscius or of Garrick, of Talma or of Siddons. Nobody, indeed, was better aware of this than the noble-minded Shakspeare; and feelingly he has breathed forth in his sonnets this conscious oppression under which he lay of public opinion, unfavourable by a double title to his own pretensions; for, being both dramatic author and dramatic performer, he found himself heir to a two-fold opprobrium, and at an era of English society when the weight of that opprobrium was heaviest. In reality, there was at this period a collision of forces acting in opposite directions upon the estimation of the stage and scenical art, and therefore of all the ministers in its equipage. Puritanism frowned upon these pursuits, as ruinous to public morals; on the other hand, loyalty could not but tolerate what was patronized by the sovereign; and it happened that Elizabeth, James, and Charles I., were all alike lovers and promoters of theatrical amusements, which were indeed more indispensable to the relief of court ceremony, and the monotony of aulic pomp, than in any other region of life. This royal support, and the consciousness that any brilliant success in these arts implied an unusual share of natural endowments, did something in mitigation of a scorn which must else have been intolerable to all generous natures.

But whatever prejudice might thus operate against the perfect sanctity of Shakspeare's posthumous reputation, it is certain that the splendour of his worldly success must have done much to obliterate that effect; his admirable colloquial talents a good deal, and his gracious affability still more. The wonder therefore will still remain, that Betterton, in less than a century from his death, should have been able to glean so little. And for the solution of this wonder we must throw ourselves chiefly upon the explanations we have made as to the parliamentary war, and the local ravages of its progress in the very district, of the very town, and the very house.

If further arguments are still wanted to explain this mysterious abolition, we may refer the reader to the following succession of disastrous events, by which it should seem that a perfect malice of misfortune pursued the vestiges of the mighty poet's steps. In 1613, the Globe theatre, with which he had been so long connected, was burned to the ground. Soon afterwards a great fire occurred in Stratford; and next (without counting upon the fire of London, just fifty years after his death, which, however, would consume many an important record from periods far more remote), the house of Ben Jonson, in which probably, as Mr Campbell suggests, might be parts of his correspondence, was also burned. Finally, there was an old tradition that Lady Barnard, the sole grand-daughter of Shakspeare, had carried off many of his papers from Stratford; and these papers have never since been traced.

In many of the elder lives it has been asserted, that John Shakspeare, the father of the poet, was a butcher, and in others that he was a woolstapler. It is now settled beyond dispute that he was a glover. This was his professed occupation in Stratford, though it is certain that, with this leading trade, from which he took his denomination, he combined some collateral pursuits; and it is possible enough that, as openings offered, he may have meddled with many. In that age, and in a provincial town, nothing like the exquisite subdivision of labour was attempted which we now see realized in the great cities of Christendom. And one trade is often found to play into another with so much reciprocal advantage, that even in our own days we do not much wonder at an enterprising man, in country places, who combines several in his own person. Accordingly John Shakspeare is known to have united with his town calling the rural and miscellaneous occupations of a farmer.

---

[1] In fact, by way of representing to himself the system or scheme of the English roads, the reader has only to imagine one great letter X, or a St Andrew's cross, laid down from north to south, and decussating at Birmingham. Even Coventry, which makes a slight variation for one or two roads, and so far disturbs this decussation, by shifting it eastwards, is still in Warwickshire.

Meantime his avowed business stood upon a very different footing from the same trade as it is exercised in modern times. Gloves were in that age an article of dress more costly by much, and more elaborately decorated, than in our own. They were a customary present from some cities to the judges of assize, and to other official persons; a custom of ancient standing, and in some places, we believe, still subsisting; and in such cases it is reasonable to suppose that the gloves must originally have been more valuable than the trivial modern article of the same name. So also, perhaps, in their origin, of the gloves given at funerals. In reality, whenever the simplicity of an age makes it difficult to renew the parts of a wardrobe except in capital towns of difficult access, prudence suggests that such wares should be manufactured of more durable materials; and, being so, they become obviously susceptible of more lavish ornament. But it will not follow, from this essential difference in the gloves of Shakspeare's age, that the glover's occupation was more lucrative. Doubtless he sold more costly gloves, and upon each pair had a larger profit; but for that very reason he sold fewer. Two or three gentlemen "of worship" in the neighbourhood might occasionally require a pair of gloves, but it is very doubtful whether any inhabitant of Stratford would ever call for so mere a luxury.

The practical result, at all events, of John Shakspeare's various pursuits does not appear permanently to have met the demands of his establishment; and in his maturer years there are indications still surviving that he was under a cloud of embarrassment. He certainly lost at one time his social position in the town of Stratford; but there is a strong presumption, in *our* construction of the case, that he finally retrieved it; and for this retrieval of a station which he had forfeited by personal misfortunes or neglect, he was altogether indebted to the filial piety of his immortal son.

Meantime the earlier years of the elder Shakspeare wore the aspect of rising prosperity, however unsound might be the basis on which it rested. There can be little doubt that William Shakspeare, from his birth up to his tenth or perhaps his eleventh year, lived in careless plenty, and saw nothing in his father's house but that style of liberal housekeeping which has ever distinguished the upper yeomanry and the rural gentry of England. Probable enough it is that the resources for meeting this liberality were not strictly commensurate with the family income, but were sometimes allowed to entrench, by means of loans or mortgages, upon capital funds. The stress upon the family finances was perhaps at times severe; and that it was borne at all, must be imputed to the large and even splendid portion which John Shakspeare received with his wife.

This lady, for such she really was in an eminent sense, by birth as well as by connections, bore the beautiful name of Mary Arden, a name derived from the ancient forest district[1] of the county; and doubtless she merits a more elaborate notice than our slender materials will furnish. To have been *the mother of Shakspeare*,—how august a title to the reverence of infinite generations, and of centuries beyond the vision of prophecy. A plausible hypothesis has been started in modern times, that the facial structure, and that the intellectual conformation, may be deduced more frequently from the corresponding characteristics in the mother than in the father. It is certain that no very great man has ever existed, but that his greatness has been rehearsed and predicted in one or other of his parents. And it cannot be denied, that in the most eminent men, where we have had the means of pursuing the investigation, the mother has more frequently been repeated and reproduced than the father. We have known cases where the mother has furnished all the intellect, and the father all the moral sensibility; upon which assumption, the wonder ceases that Cicero, Lord Chesterfield, and other brilliant men, who took the utmost pains with their sons, should have failed so conspicuously; for possibly the mothers had been women of excessive and even exemplary stupidity. In the case of Shakspeare, each parent, if we had any means of recovering their characteristics, could not fail to furnish a study of the most profound interest; and with regard to his mother in particular, if the modern hypothesis be true, and if we are indeed to deduce from *her* the stupendous intellect of her son, in that case she must have been a benefactress to her husband's family beyond the promises of fairyland or the dreams of romance; for it is certain that to her chiefly this family was also indebted for their worldly comfort.

Mary Arden was the youngest daughter and the heiress of Robert Arden of Wilmecote, Esq. in the county of Warwick. The family of Arden was even then of great antiquity. About one century and a quarter before the birth of William Shakspeare, a person bearing the same name as his maternal grandfather had been returned by the commissioners in their list of the Warwickshire gentry; he was there styled Robert Arden, Esq. of Bromich. This was in 1433, or the 12th year of Henry VI. In Henry VII.'s reign, the Ardens received a grant of lands from the crown; and in 1568, four years after the birth of William Shakspeare, Edward Arden, of the same family, was sheriff of the county. Mary Arden was therefore a young lady of excellent descent and connections, and an heiress of considerable wealth. She brought to her husband, as her marriage portion, the landed estate of Asbies, which, upon any just valuation, must be considered as a handsome dowry for a woman of her station. As this point has been contested, and as it goes a great way towards determining the exact social position of the poet's parents, let us be excused for sifting it a little more narrowly than might else seem warranted by the proportions of our present life. Every question which it can be reasonable to raise at all, it must be reasonable to treat with at least so much of minute research as may justify the conclusions which it is made to support.

The estate of Asbies contained fifty acres of arable land, six of meadow, and a right of commonage. What may we assume to have been the value of its fee-simple? Malone, who allows the total fortune of Mary Arden to have been L.110. 13s. 4d., is sure that the value of Asbies could not have been more than one hundred pounds. But why? Because, says he, the "average" rent of land at that time was no more than three shillings per acre. This we deny; but upon that assumption, the total yearly rent of fifty-six acres would be exactly eight guineas.[1] And therefore, in assigning the value of Asbies at one hundred pounds, it appears that Malone must have estimated the land at no more than twelve years' purchase, which would carry the value to L.100. 16s. "Even at this estimate," as the latest annotator[2] on this subject *justly* observes, "Mary Arden's portion was a larger one than was usually given to a landed gentleman's daughter." But this writer objects to Malone's principle of valuation. "We find," says he, "that John Shakspeare also farmed the meadow of Tugton, containing sixteen acres, at the rate of eleven shillings per acre. Now what proof has Mr Malone adduced that the acres of Asbies were not as valuable as those of Tugton? And if they were so, the former estate must have been worth between three and four hundred pounds." In the main drift of his objections we concur with Mr Campbell. But as they are liable to some criticism, let us clear the ground of all plausible cavils, and then see what will be the result. Malone, had he been alive, would probably have answered, that Tugton was a farm specially privileged by nature; and that if any man contended for so unusual a rent as eleven shillings an acre for land not known to him, the *onus probandi* would lie upon *him*. Be it so; eleven shillings is certainly above the ordinary level of rent, but three shillings is below it. We contend, that for tolerably good land, situated advantageously, that is, with a ready access to good markets and good fairs, such as those of Coventry, Birmingham, Gloucester, Worcester, Shrewsbury, &c., one noble might be assumed as the annual rent; and that in such situations twenty years' purchase was not a valuation, even in Elizabeth's reign, very unusual. Let us, however, assume the rent at only five shillings, and land at sixteen years' purchase: upon this basis, the rent would be L.14, and the value of the fee-simple L.224. Now, if it were required to equate that sum with its present value, a very operose[3] calculation might be requisite. But contenting ourselves with the gross method of making such equations between 1560 and the current century, that is, multiplying by five, we shall find the capital value of the estate to be eleven hundred and twenty pounds, whilst the annual rent would be exactly seventy. But if the estate had been sold, and the purchase-money lent upon mortgage (the only safe mode of investing money at that time), the annual interest would have reached L.28, equal to L.140 of modern money; for mortgages in Elizabeth's age readily produced ten per cent.

---

[1] And probably so called by some remote ancestor who had emigrated from the forest of Ardennes, in the Netherlands, and *now* for ever memorable to English ears from its proximity to Waterloo.

A woman who should bring at this day an annual income of L.140 to a provincial tradesman, living in a sort of *rus in urbe*, according to the simple fashions of rustic life, would assuredly be considered as an excellent match. And there can be little doubt that Mary Arden's dowry it was which, for some ten or a dozen years succeeding to his marriage, raised her husband to so much social consideration in Stratford. In 1550 John Shakspeare is supposed to have first settled in Stratford, having migrated from some other part of Warwickshire. In 1557 he married Mary Arden; in 1565, the year subsequent to the birth of his son William, his third child, he was elected one of the aldermen; and in the year 1568 he became first magistrate of the town, by the title of high bailiff. This year we may assume to have been that in which the prosperity of this family reached its zenith; for in this year it was, over and above the presumptions furnished by his civic honours, that he obtained a grant of arms from Clarencieux of the Heralds' College. On this occasion he declared himself worth five hundred pounds derived from his ancestors. And we really cannot understand the right by which critics, living nearly three centuries from his time, undertake to know his affairs better than himself, and to tax him with either inaccuracy or falsehood. No man would be at leisure to court heraldic honours when he knew himself to be embarrassed, or apprehended that he soon might be so. A man whose anxieties had been fixed at all upon his daily livelihood would, by this chase after the aërial honours of heraldry, have made himself a butt for ridicule such as no fortitude could enable him to sustain.

In 1568, therefore, when his son William would be moving through his fifth year, John Shakspeare (now honoured by the designation of *Master*) would be found at times in the society of the neighbouring gentry. Ten years in advance of this period he was already in difficulties. But there is no proof that these difficulties had then reached a point of degradation, or of memorable distress. The sole positive indications of his decaying condition are, that in 1578 he received an exemption from the small weekly assessment levied upon the aldermen of Stratford for the relief of the poor; and that in the following year, 1579, he is found enrolled amongst the defaulters in the payment of taxes. The latter fact undoubtedly goes to prove that, like every man who is falling back in the world, he was occasionally in arrears. Paying taxes is not like the honours awarded or the processions regulated by Clarencieux; no man is ambitious of precedency there; and if a laggard pace in that duty is to be received as evidence of pauperism, nine tenths of the English people might occasionally be classed as paupers. With respect to his liberation from the weekly assessment, that may bear a construction different from the one which it has received. This payment, which could never have been regarded as a burthen, not amounting to five pounds annually of our present money, may have been held up as an exponent of wealth and consideration; and John Shakspeare may have been required to resign it as an honourable distinction, not suitable to the circumstances of an embarrassed man. Finally, the fact of his being indebted to Robert Sadler, a baker, in the sum of five pounds, and his being under the necessity of bringing a friend as security for the payment, proves nothing at

---

[1] Let not the reader impute to us the gross anachronism of making an estimate for Shakspeare's days in a coin which did not exist until a century, within a couple of years, after Shakspeare's birth, and did not settle to the value of twenty-one shillings until a century after his death. The nerve of such an anachronism would lie in putting the estimate into a mouth of that age. And this is precisely the blunder into which the foolish forger of Vortigern, &c. has fallen. He does not indeed directly mention guineas; but indirectly and virtually he does, by repeatedly giving us accounts imputed to Shakspearian contemporaries, in which the sum-total amounts to L.5. 5s.; or to L.26. 5s.; or, again, to L.17. 17s. 6d. A man is careful to subscribe L.14. 14s. and so forth. But how could such amounts have arisen unless under a secret reference to guineas, which were not in existence until Charles II.'s reign; and, moreover, to guineas at their final settlement by law into twenty-one shillings each, which did not take place until George I.'s reign.

[2] Thomas Campbell the poet, in his eloquent Remarks on the Life and Writings of William Shakspeare, prefixed to a popular edition of the poet's dramatic works. London, 1838.

[3] After all the assistance given to such equations between different times or different places by Sir George Shuckborough's tables, and other similar investigations, it is still a very difficult problem, complex, and, after all, merely tentative in the results, to assign the true value in such cases; not only for the obvious reason, that the powers of money have varied in different directions with regard to different objects, and in different degrees where the direction has on the whole continued the same, but because the very objects to be taken into computation are so indeterminate, and vary so much, not only as regards century and century, kingdom and kingdom, but also, even in the same century and the same kingdom, as regards rank and rank. That which is a mere necessary to one, is a luxurious superfluity to another. And, in order to ascertain these differences, it is an indispensable qualification to have studied the habits and customs of the several classes concerned, together with the variations of those habits and customs.

all. There is not a town in Europe in which opulent men cannot be found that are backward in the payment of their debts. And the probability is, that Master Sadler acted like most people who, when they suppose a man to be going down in the world, feel their respect for him sensibly decaying, and think it wise to trample him under foot, provided only in that act of trampling they can squeeze out of him their own individual debt. Like that terrific chorus in Spohr's oratorio of St Paul, "*stone him to death*" is the cry of the selfish and the illiberal amongst creditors, alike towards the just and the unjust amongst debtors.

It was the wise and beautiful prayer of Agar, "Give me neither poverty nor riches;" and, doubtless, for quiet, for peace, and the *latentis semita vitæ*, that is the happiest dispensation. But, perhaps, with a view to a school of discipline and of moral fortitude, it might be a more salutary prayer, "Give me riches *and* poverty, and afterwards neither." For the transitional state between riches and poverty will teach a lesson both as to the baseness and the goodness of human nature, and will impress that lesson with a searching force, such as no borrowed experience ever can approach. Most probable it is that Shakspeare drew some of his powerful scenes in the Timon of Athens, those which exhibit the vileness of ingratitude and the impassioned frenzy of misanthropy, from his personal recollections connected with the case of his own father. Possibly, though a cloud of 270 years now veils it, this very Master Sadler, who was so urgent for his five pounds, and who so little apprehended that he should be called over the coals for it in the Encyclopædia Britannica, may have sate for the portrait of that Lucullus who says of Timon—

> Alas, good lord! a noble gentleman 'tis, if he would not keep so good a house. Many a time and often I have dined with him, and told him on't; and come again to supper to him, of purpose to have him spend less: and yet he would embrace no counsel, take no warning by my coming. Every man has his fault, and honesty is his; I have told him on't, but I could never get him from it.

For certain years, perhaps, John Shakspeare moved on in darkness and sorrow:

> His familiars from his buried fortunes
> Slunk all away; left their false vows with him,
> Like empty purses pick'd: and his poor self,
> A dedicated beggar to the air,
> With his disease of all-shunn'd poverty,
> Walk'd, like contempt, alone.

We, however, at this day are chiefly interested in the case as it bears upon the education and youthful happiness of the poet. Now if we suppose that from 1568, the high noon of the family prosperity, to 1578, the first year of their mature embarrassments, one half the interval was passed in stationary sunshine, and the latter half in the gradual twilight of declension, it will follow that the young William had completed his tenth year before he heard the first signals of distress; and for so long a period his education would probably be conducted on as liberal a scale as the resources of Stratford would allow. Through this earliest section of his life he would undoubtedly rank as a gentleman's son, possibly as the leader of his class, in Stratford. But what rank he held through the next ten years, or, more generally, what was the standing in society of Shakspeare until he had created a new station for himself by his own exertions in the metropolis, is a question yet unsettled, but which has been debated as keenly as if it had some great dependencies. Upon this we shall observe, that could we by possibility be called to settle beforehand what rank were best for favouring the development of intellectual powers, the question might wear a face of deep practical importance; but when the question is simply as to a matter of fact, what *was* the rank held by a man whose intellectual development has long ago been completed, this becomes a mere question of curiosity. The tree has fallen; it is confessedly the noblest of all the forest; and we must therefore conclude that the soil in which it flourished was either the best possible, or, if not so, that any thing bad in its properties had been disarmed and neutralized by the vital forces of the plant, or by the benignity of nature. If any future Shakspeare were likely to arise, it might be a problem of great interest to agitate, whether the condition of a poor man or of a gentleman were best fitted to nurse and stimulate his faculties. But for the actual Shakspeare, since what he was he was, and since nothing greater can be imagined, it is now become a matter of little moment whether his course lay for fifteen or twenty years through the humilities of absolute poverty, or through the chequered paths of gentry lying in the shade. Whatever *was*, must, in this case at least, have been the best, since it terminated in producing Shakspeare; and thus far we must all be optimists.

Yet still, it will be urged, the curiosity is not illiberal which would seek to ascertain the precise career through which Shakspeare ran. This we readily concede; and we are anxious ourselves to contribute any thing in our power to the settlement of a point so obscure. What we have wished to protest against is the spirit of partisanship in which this question has too generally been discussed. For, whilst some with a foolish affectation of plebeian sympathies overwhelm us with the insipid commonplaces about birth and ancient descent, as honours containing nothing meritorious, and rush eagerly into an ostentatious exhibition of all the circumstances which favour the notion of a humble station and humble connections; others, with equal forgetfulness of true dignity, plead with the intemperance and partiality of a legal advocate for the pretensions of Shakspeare to the hereditary rank of gentleman. Both parties violate the majesty of the subject. When we are seeking for the sources of the Euphrates or the St Lawrence, we look for no proportions to the mighty volume of waters in that particular summit amongst the chain of mountains which embosoms its earliest fountains, nor are we shocked at the obscurity of these fountains. Pursuing the career of Mahommed, or of any man who has memorably impressed his own mind or agency upon the revolutions of mankind, we feel solicitude about the circumstances which might surround his cradle to be altogether unseasonable and impertinent. Whether he were born in a hovel or a palace, whether he passed his infancy in squalid poverty, or hedged around by the glittering spears of body-guards, as mere questions of fact may be interesting; but, in the light of either accessories or counteragencies to the native majesty of the subject, are trivial and below all philosophic valuation. So with regard to the creator of Lear and Hamlet, of Othello and Macbeth; to him from whose golden urns the nations beyond the far Atlantic, the multitude of the isles, and the generations unborn in Australian climes, even to the realms ot the rising sun (the ἀνατολαι ἠελιοιο), must in every age draw perennial streams of intellectual life, we feel that the little accidents of birth and social condition are so unspeakably below the grandeur of the theme, are so irrelevant and disproportioned to the real interest at issue, so incommensurable with any of its relations, that a biographer of Shakspeare at once denounces himself as below his subject if he can entertain such a question as seriously affecting the glory of the poet. In some legends of saints, we find that they were born with a lambent circle or golden aureola about their heads. This angelic coronet shed light alike upon the chambers of a cottage or a palace, upon the gloomy limits of a dungeon or the vast expansion of a cathedral; but the cottage, the palace, the dungeon, the cathedral, were all equally incapable of adding one ray of colour or one pencil of light to the supernatural halo.

Having therefore thus pointedly guarded ourselves from misconstruction, and consenting to entertain the question as one in which we, the worshippers of Shakspeare, have an interest of curiosity, but in which he, the object of our worship, has no interest of glory, we proceed to state what appears to us the result of the scanty facts surviving when collated with each other.

By his mother's side, Shakspeare was an authentic gentleman. By his father's he would have stood in a more dubious position; but the effect of municipal honours to raise and illustrate an equivocal rank has always been acknowledged under the popular tendencies of our English political system. From the sort of lead, therefore, which John Shakspeare took at one time amongst his fellow-townsmen, and from his rank of first magistrate, we may presume that, about the year 1568, he had placed himself at the head of the Stratford community. Afterwards he continued for some years to descend from this altitude; and the question is, at what point this gradual degradation may be supposed to have settled. Now we shall avow it as our opinion, that the composition of society in Stratford was such that, even had the Shakspeare family maintained their superiority, the main body of their daily associates must still have been found amongst persons below the rank of gentry. The poet must inevitably have mixed chiefly with mechanics and humble tradesmen, for such people composed perhaps the total community. But had there even been a gentry in Stratford, since they would have marked the distinctions of their rank chiefly by greater reserve of manners, it is probable that, after all, Shakspeare, with his enormity of delight in exhibitions of human nature, would have mostly cultivated that class of society in which the feelings are more elementary and simple, in which the thoughts speak a plainer language, and in which the restraints of factitious or conventional decorum are exchanged for the restraints of mere sexual decency. It is a noticeable fact to all who have looked upon human life with an eye of strict attention, that the abstract image of womanhood, in its loveliness, its delicacy, and its modesty, nowhere makes itself more impressive or more advantageously felt than in the humblest cottages, because it is there brought into immediate juxtaposition with the grossness of manners and the careless license of language incident to the fathers and brothers of the house. And this is more especially true in a nation of unaffected sexual gallantry,[1] such as the English and the Gothic races in general; since, under the immunity which their women enjoy from all servile labours of a coarse or out-of-doors order, by as much lower as they descend in the scale of rank, by so much more do they benefit under the force of contrast with the men of their own level. A young man of that class, however noble in appearance, is somewhat degraded in the eyes of women, by the necessity which his indigence imposes of working under a master; but a beautiful young woman, in the very poorest family, unless she enters upon a life of domestic servitude (in which case her labours are light, suited to her sex, and withdrawn from the public eye), so long in fact as she stays under her father's roof, is as perfectly her own mistress and *sui juris* as the daughter of an earl. This personal dignity, brought into stronger relief by the mercenary employments of her male connections, and the feminine gentleness of her voice and manners, exhibited under the same advantages of contrast, oftentimes combine to make a young cottage beauty as fascinating an object as any woman of any station.

Hence we may in part account for the great event of Shakspeare's early manhood, his premature marriage. It has always been known, or at least traditionally received for a fact, that Shakspeare had married whilst yet a boy; and that his wife was unaccountably older than himself. In the very earliest biographical sketch of the poet, compiled by Rowe, from materials collected by Betterton the actor, it was stated (and that statement is now ascertained to have been correct), that he had married Anne Hathaway, "the daughter of a substantial yeoman." Further than this nothing was known. But in September 1836 was published a very remarkable document, which gives the assurance of law to the time and fact of this event, yet still, unless collated with another record, does nothing to lessen the mystery which had previously surrounded its circumstances. This document consists of two parts: the first, and principal, according to the logic of the case, though second according to the arrangement, being a *license* for the marriage of William Shakspeare with Anne Hathaway, under the condition "of *once* asking of the bannes of matrimony," that is, in effect, dispensing with two out of the three customary askings; the second or subordinate part of the document being a *bond* entered into by two sureties, viz. Fulke Sandells and John Rychardson, both described as *agricolæ* or yeomen, and both marksmen (that is, incapable of writing, and therefore subscribing by means of *marks*), for the payment of forty pounds sterling, in the event of Shakspeare, yet a minor, and incapable of binding himself, failing to fulfil the conditions of the license. In the bond, drawn up in Latin, there is no mention of Shakspeare's name; but in the license, which is altogether English, *his* name, of course, stands foremost; and as it may gratify the reader to see the very words and orthography of the original, we here extract the *operative* part of this document, prefacing only, that the license is attached by way of explanation to the bond. "The condition of this obligation is suche, that if herafter there shall not appere any lawfull lett or impediment, by reason of any precontract, &c., but that Willm. Shagspere, one thone ptie" [on the one party), "and Anne Hathwey of Stratford, in the diocess of Worcester, maiden, may lawfully solemnize matrimony together; and in the same afterwards remaine and continew like man and wiffe. And, moreover, if the said Willm. Shagspere do not proceed to solemnization of mariadg with the said Anne Hathwey, without the consent of hir frinds;—then the said obligation" [viz. to pay forty pounds] "to be voyd and of none effect, or els to stand & abide in full force and vertue."

---

[1] Never was the *esse quam videri* in any point more strongly discriminated than in this very point of gallantry to the female sex, as between England and France. In France, the verbal homage to woman is so excessive as to betray its real purpose, viz. that it is a mask for secret contempt. In England, little is *said*; but, in the mean time, we allow our sovereign ruler to be a woman; which in France is impossible. Even that fact is of some importance, but less so than what follows. In every country whatsoever, if any principle has a deep root in the moral feelings of the people, we may rely upon its showing itself, by a thousand evidences, amongst the very lowest ranks, and in their daily intercourse, and their *undress* manners. Now in England there is, and always has been, a manly feeling, most widely diffused, of unwillingness to see labours of a coarse order, or requiring muscular exertions, thrown upon women. Pauperism, amongst other evil effects, has sometimes locally disturbed this predominating sentiment of Englishmen; but never at any time with such depth as to kill the root of the old hereditary manliness. Sometimes at this day a gentleman, either from carelessness, or from over-ruling force of convenience, or from real defect of gallantry, will allow a female servant to carry his portmanteau for him; though, after all, that spectacle is a rare one. And everywhere women of all ages engage in the pleasant, nay elegant, labours of the hay field; but in Great Britain women are never suffered to mow, which is a most athletic and exhausting labour, nor to load a cart, nor to drive a plough or hold it. In France, on the other hand, before the Revolution (at which period the pseudo-homage, the lip-honour, was far more ostentatiously professed towards the female sex than at present), a Frenchman of credit, and vouching for his statement by the whole weight of his name and personal responsibility (M. Simond, now an American citizen), records the following abominable scene as one of no uncommon occurrence: A woman was in some provinces yoked side by side with an ass to the plough or the harrow; and M. Simond protests that it excited no horror to see the driver distributing his lashes impartially between the woman and her brute yoke-fellow. So much for the wordy pomps of French gallantry. In England, we trust, and we believe, that any man, caught in such a situation, and in such an abuse of his power (supposing the case otherwise a possible one), would be killed on the spot.

What are we to think of this document? Trepidation and anxiety are written upon its face. The parties are not to be married by a special license; not even by an ordinary license; in that case no proclamation of banns, no public asking at all, would have been requisite. Economical scruples are consulted; and yet the regular movement of the marriage "through the bell-ropes"[1] is disturbed. Economy, which retards the marriage, is here evidently in collision with some opposite principle which precipitates it. How is all this to be explained? Much light is afforded by the date when illustrated by another document. The bond bears date on the 28th day of November in the 25th year of our lady the queen, that is, in 1582. Now the baptism of Shakspeare's eldest child, Susanna, is registered on the 26th of May in the year following. Suppose, therefore, that his marriage was solemnized on the 1st day of December; it was barely possible that it could be earlier, considering that the sureties, drinking, perhaps, at Worcester throughout the 28th of November, would require the 29th, in so dreary a season, for their return to Stratford; after which some preparation might be requisite to the bride, since the marriage was *not* celebrated at Stratford. Next suppose the birth of Miss Susanna to have occurred, like her father's, two days before her baptism, viz. on the 24th of May. From December the 1st to May the 24th, both days inclusively, are 175 days; which, divided by seven, gives precisely twenty-five weeks, that is to say, six months short by one week. Oh, fie, Miss Susanna, you came rather before you were wanted.

Mr Campbell's comment upon the affair is, that "*if* this was the case," viz. if the baptism were really solemnized on the 26th of May, "the poet's first child would *appear* to have been born only six months and eleven days after the bond was entered into." And he then concludes that, on this assumption, "Miss Susanna Shakspeare came into the world a little prematurely." But this is to doubt where there never was any ground for doubting; the baptism was *certainly* on the 26th of May; and, in the next place, the calculation of six months and eleven days is sustained by substituting lunar months for calendar, and then only by supposing the marriage to have been celebrated on the very day of subscribing the bond in Worcester, and the baptism to have been coincident with the birth; of which suppositions the latter is improbable, and the former, considering the situation of Worcester, impossible.

Strange it is, that, whilst all biographers have worked with so much zeal upon the most barren dates or most baseless traditions in the great poet's life, realising in a manner the chimeras of Laputa, and endeavouring "to extract sunbeams from cucumbers," such a story with regard to such an event, no fiction of village scandal, but involved in legal documents, a story so significant and so eloquent to the intelligent, should formerly have been dismissed without notice of any kind, and even now, after the discovery of 1836, with nothing beyond a slight conjectural insinuation. For our parts, we should have been the last amongst the biographers to unearth any forgotten scandal, or, after so vast a lapse of time, and when the grave had shut out all but charitable thoughts, to point any moral censures at a simple case of natural frailty, youthful precipitancy of passion, of all trespasses the most venial, where the final intentions are honourable. But in this case there seems to have been something more in motion than passion or the ardour of youth. "I like not," says Parson Evans (alluding to Falstaff in masquerade), "I like not when a woman has a great peard; I spy a great peard under her muffler." Neither do we like the spectacle of a mature young woman, five years past her majority, wearing the semblance of having been led astray by a boy who had still two years and a half to run of his minority. Shakspeare himself, looking back on this part of his youthful history from his maturest years, breathes forth pathetic counsels against the errors into which his own inexperience had been ensnared. The disparity of years between himself and his wife he notices in a beautiful scene of the Twelfth Night. The Duke Orsino, observing the sensibility which the pretended Cesario had betrayed on hearing some touching old snatches of a love strain, swears that his beardless page must have felt the passion of love, which the other admits. Upon this the dialogue proceeds thus:

Duke. What kind of woman is't?
Viola. Of your complexion.
Duke. She is not worth thee then:—What years?
Viola. I' faith,
About your years, my lord.
Duke. Too old, by heaven. *Let still the woman take*
An elder than herself: so wears she to him,
So sways she level in her husband's heart.
For, boy, however we do praise ourselves,
Our fancies are more giddy and unfirm,
More longing, wavering, sooner lost and worn,
Than women's are.
Viola. I think it well, my lord.
Duke. Then *let thy love be younger than thyself,*
Or thy affection cannot hold the bent;
For women are as roses, whose fair flower,
Being once display'd, doth fall that very hour.

These counsels were uttered nearly twenty years after the event in his own life to which they probably look back; for this play is supposed to have been written in Shakspeare's thirty-eighth year. And we may read an earnestness in pressing the point as to the *inverted* disparity of years, which indicates pretty clearly an appeal to the lessons of his personal experience. But his other indiscretion, in having yielded so far to passion and opportunity as to crop by prelibation, and before they were hallowed, those flowers of paradise which belonged to his marriage-day; this he adverts to with even more solemnity of sorrow, and with more pointed energy of moral reproof, in the very last drama which is supposed to have proceeded from his pen, and therefore with the force and sanctity of testamentary counsel. The Tempest is all but ascertained to have been composed in 1611, that is, about five years before the poet's death; and indeed could not have been composed much earlier; for the very incident which suggested the basis of the plot, and of the local scene, viz. the shipwreck of Sir George Somers on the Bermudas (which were in consequence denominated the Somers' Islands), did not occur until the year 1609. In the opening of the fourth act, Prospero formally betrothes his daughter to Ferdinand; and in doing so he pays the prince a well-merited compliment of having "worthily purchas'd" this rich jewel, by the patience with which, for her sake, he had supported harsh usage, and other painful circumstances of his trial. But, he adds solemnly,

If thou dost break her virgin knot before
All sanctimonious ceremonies may
With full and holy rite be minister'd;

---

[1] Amongst people of humble rank in England, who only were ever asked in church, until the new-fangled systems of marriage came up within the last ten or fifteen years, during the currency of the three Sundays on which the banns were proclaimed by the clergyman from the reading desk, the young couple elect were said jocosely to be "hanging in the bell-ropes;" alluding perhaps to the joyous peal contingent on the final completion of the marriage.

in that case what would follow?

> No sweet aspersion shall the heavens let fall,
> To make this contract grow; *but barren hate,*
> *Sour-ey'd disdain and discord, shall bestrew*
> *The union of your bed with weeds so loathly*
> *That you shall hate it both.* Therefore take heed,
> As Hymen's lamps shall light you.

The young prince assures him in reply, that no strength of opportunity, concurring with the uttermost temptation, not

> the murkiest den,
> The most opportune place, the strong'st suggestion
> Our worser genius can———

should ever prevail to lay asleep his jealousy of self-control, so as to take any advantage of Miranda's innocence. And he adds an argument for this abstinence, by way of reminding Prospero, that not honour only, but even prudential care of his own happiness, is interested in the observance of his promise. Any unhallowed anticipation would, as he insinuates,

> take away
> The edge of that day's celebration,
> When I shall think, or Phœbus' steeds are founder'd,
> Or night kept chain'd below;

that is, when even the winged hours would seem to move too slowly. Even thus Prospero is not quite satisfied: during his subsequent dialogue with Ariel, we are to suppose that Ferdinand, in conversing apart with Miranda, betrays more impassioned ardour than the wise magician altogether approves. The prince's caresses have not been unobserved; and thus Prospero renews his warning:

> Look thou be true: do not give dalliance
> Too much the rein: the strongest oaths are straw
> To the fire i' the blood: be more abstemious,
> Or else—good night your vow.

The royal lover re-assures him of his loyalty to his engagements; and again the wise father, so honourably jealous for his daughter, professes himself satisfied with the prince's pledges.

Now in all these emphatic warnings, uttering the language "of that sad wisdom folly leaves behind," who can avoid reading, as in subtile hieroglyphics, the secret record of Shakspeare's own nuptial disappointments? We, indeed, that is, universal posterity through every age, have reason to rejoice in these disappointments; for to them, past all doubt, we are indebted for Shakspeare's subsequent migration to London, and his public occupation, which, giving him a deep pecuniary interest in the productions of his pen, such as no other literary application of his powers could have approached in that day, were eventually the means of drawing forth those divine works which have survived their author for our everlasting benefit.

Our own reading and deciphering of the whole case is as follows. The Shakspeares were a handsome family, both father and sons. This we assume upon the following grounds: First, on the presumption arising out of John Shakspeare's having won the favour of a young heiress higher in rank than himself; secondly, on the presumption involved in the fact of three amongst his four sons having gone upon the stage, to which the most obvious (and perhaps in those days a *sine qua non*) recommendation would be a good person and a pleasing countenance; thirdly, on the direct evidence of Aubrey, who assures us that William Shakspeare was a handsome and a well-shaped man; fourthly, on the implicit evidence of the Stratford monument, which exhibits a man of good figure and noble countenance; fifthly, on the confirmation of this evidence by the Chandos portrait, which exhibits noble features, illustrated by the utmost sweetness of expression; sixthly, on the selection of theatrical parts, which it is known that Shakspeare personated, most of them being such as required some dignity of form, viz. kings, the athletic (though aged) follower of an athletic young man, and supernatural beings. On these grounds, direct or circumstantial, we believe ourselves warranted in assuming that William Shakspeare was a handsome and even noble-looking boy. Miss Anne Hathaway had herself probably some personal attractions; and, if an indigent girl, who looked for no pecuniary advantages, would probably have been early sought in marriage. But as the daughter of "a substantial yeoman," who would expect some fortune in his daughter's suitors, she had, to speak coarsely, a little outlived her market. Time she had none to lose. William Shakspeare pleased her eye; and the gentleness of his nature made him an apt subject for female blandishments, possibly for female arts. Without imputing, however, to this Anne Hathaway any thing so hateful as a settled plot for ensnaring him, it was easy enough for a mature woman, armed with such inevitable advantages of experience and of self-possession, to draw onward a blushing novice; and, without directly creating opportunities, to place him in the way of turning to account such as naturally offered. Young boys are generally flattered by the condescending notice of grown-up women; and perhaps Shakspeare's own lines upon a similar situation, to a young boy adorned with the same natural gifts as himself, may give us the key to the result:

> Gentle thou art, and therefore to be won;
> Beauteous thou art, therefore to be assail'd;
> And, when a woman woos, what woman's son
> Will sourly leave her till he have prevail'd?

Once, indeed, entangled in such a pursuit, any person of manly feelings would be sensible that he had no retreat: *that* would be—to insult a woman, grievously to wound her sexual pride, and to insure her lasting scorn and hatred. These were consequences which the gentle-minded Shakspeare could not face: he pursued his good fortunes, half perhaps in heedlessness, half in desperation, until he was roused by the clamorous displeasure of her family upon first discovering the situation of their kinswoman. For such a situation there could be but one atonement, and that was hurried forward by both parties; whilst, out of delicacy towards the bride, the wedding was not celebrated in Stratford (where the register contains no notice of such an event); nor, as Malone imagined, in Weston-upon-Avon, that being in the diocese of Gloucester; but in some parish, as yet undiscovered, in the diocese of Worcester.

But now arose a serious question as to the future maintenance of the young people. John Shakspeare was depressed in his circumstances, and he had other children besides William, viz. three sons and a daughter. The elder lives have represented him as burdened with ten; but this was an error, arising out of the confusion between John Shakspeare the glover and John Shakspeare a shoemaker. This error has been thus far of use, that, by exposing the fact of two John Shakspeares (not kinsmen) residing in Stratford-upon-Avon, it has satisfactorily proved the name to be amongst those which are locally indigenous to Warwickshire. Meantime it is now ascertained that John Shakspeare the glover had only eight children, viz. four daughters and four sons. The order of their succession was this: Joan, Margaret, WILLIAM, Gilbert, a second Joan, Anne, Richard, and Edmund. Three of the daughters, viz. the two eldest of the family, Joan and Margaret, together with Anne, died in childhood: all the rest attained mature ages, and of these William was the eldest. This might give him some advantage in his father's regard; but in a question of pecuniary provision precedency amongst the children of an insolvent is nearly nominal. For the present John Shakspeare could do little for his son; and, under these circumstances, perhaps the father of Anne Hathaway would come forward to assist the new-married couple. This condition of dependency would furnish matter for painful feelings and irritating words: the youthful husband, whose mind would be expanding as rapidly as the leaves and blossoms of spring-time in polar latitudes, would soon come to appreciate the sort of wiles by which he had been caught. The female mind is quick, and almost gifted with the power of witchcraft, to decipher what is passing in the thoughts of familiar companions. Silent and forbearing as William Shakspeare might be, Anne, his staid wife, would read his secret reproaches; ill would she dissemble her wrath, and the less so from the consciousness of having deserved them. It is no uncommon case for women to feel anger in connection with one subject, and to express it in connection with another; which other, perhaps (except as a serviceable mask), would have been a matter of indifference to their feelings. Anne would therefore reply to those inevitable reproaches which her own sense must presume to be lurking in her husband's heart, by others equally stinging, on his inability to support his family, and on his obligations to her father's purse. Shakspeare, we may be sure, would be ruminating every hour on the means of his deliverance from so painful a dependency; and at length, after four years' conjugal discord, he would resolve upon that plan of solitary emigration to the metropolis, which, at the same time that it released him from the humiliation of domestic feuds, succeeded so splendidly for his worldly prosperity, and with a train of consequences so vast for all future ages.

Such, we are persuaded, was the real course of Shakspeare's transition from school-boy pursuits to his public career: and upon the known temperament of Shakspeare, his genial disposition to enjoy life without disturbing his enjoyment by fretting anxieties, we build the conclusion, that had his friends furnished him with ampler funds, and had his marriage been well assorted or happy, we—the world of posterity—should have lost the whole benefit and delight which we have since reaped from his matchless faculties. The motives which drove him *from* Stratford are clear enough; but what motives determined his course *to* London, and especially to the stage, still remains to be explained. Stratford-upon-Avon, lying in the high road from London through Oxford to Birmingham (or more generally to the north), had been continually visited by some of the best comedians during Shakspeare's childhood. One or two of the most respectable metropolitan actors were natives of Stratford. These would be well known to the elder Shakspeare. But, apart from that accident, it is notorious that mere legal necessity and usage would compel all companies of actors, upon coming into any town, to seek, in the first place, from the chief magistrate, a license for opening a theatre, and next, over and above this public sanction, to seek his personal favour and patronage. As an alderman, therefore, but still more whilst clothed with the official powers of chief magistrate, the poet's father would have opportunities of doing essential services to many persons connected with the London stage. The conversation of comedians acquainted with books, fresh from the keen and sparkling circles of the metropolis, and filled with racy anecdotes of the court, as well as of public life generally, could not but have been fascinating, by comparison with the stagnant society of Stratford. Hospitalities on a liberal scale would be offered to these men: not impossibly this fact might be one principal key to those dilapidations which the family estate had suffered. These actors, on *their* part, would retain a grateful sense of the kindness they had received, and would seek to repay it to John Shakspeare, now that he was depressed in his fortunes, as opportunities might offer. His eldest son, growing up a handsome young man, and beyond all doubt from his earliest days of most splendid colloquial powers (for assuredly of *him* it may be taken for granted,

> Nec licuit populis parvum te, Nile, videre),

would be often reproached in a friendly way for burying himself in a country life. These overtures, prompted alike by gratitude to the father, and a real selfish interest in the talents of the son, would at length take a definite shape; and, upon some clear understanding as to the terms of such an arrangement, William Shakspeare would at length (about 1586, according to the received account, that is, in the fifth year of his married life, and the twenty-third or twenty-fourth of his age), unaccompanied by wife or children, translate himself to London. Later than 1586 it could not well be; for already in 1589 it has been recently ascertained that he held a share in the property of a leading theatre.

We must here stop to notice, and the reader will allow us to notice with summary indignation, the slanderous and idle tale which represents Shakspeare as having fled to London in the character of a criminal, from the persecutions of Sir Thomas Lucy of Charlecot. This tale has long been propagated under two separate impulses: chiefly, perhaps, under the vulgar love of pointed and glaring contrasts; the splendour of the man was in this instance brought into a sort of epigrammatic antithesis with the humility of his fortunes; secondly, under a baser impulse, the malicious pleasure of seeing a great man degraded. Accordingly, as in the case of Milton,[1] it has been affirmed that Shakspeare had suffered corporal chastisement, in fact (we abhor to utter such words), that he had been judicially whipped. Now, first of all, let us mark the inconsistency of this tale: the poet was whipped, that is, he was punished most disproportionately, and yet he fled to avoid punishment. Next, we are informed that his offence was deer-stealing, and from the park of Sir Thomas Lucy. And it has been well ascertained that Sir Thomas had no deer, and had no park. Moreover, deer-stealing was regarded by our ancestors exactly as poaching is regarded by us. Deer ran wild in all the great forests; and no offence was looked upon as so venial, none so compatible with a noble Robin-Hood style of character, as this very trespass upon what were regarded as *feræ naturæ*, and not at all as domestic property. But had it been otherwise, a trespass was not punishable with whipping; nor had Sir Thomas Lucy the power to irritate a whole community like Stratford-upon-Avon, by branding with permanent disgrace a young man so closely connected with three at least of the best families in the neighbourhood. Besides, had Shakspeare suffered any dishonour of that kind, the scandal would infallibly have pursued him at his very heels to London; and in that case Greene, who has left on record, in a posthumous work of 1592, his malicious feelings towards Shakspeare, could not have failed to notice it. For, be it remembered, that a judicial flagellation contains a twofold ignominy: flagellation is ignominious in its own nature, even though unjustly inflicted, and by a ruffian; secondly, any judicial punishment is ignominious, even though not wearing a shade of personal degradation. Now a judicial flagellation includes both features of dishonour. And is it to be imagined that an enemy, searching with the diligence of malice for matter against Shakspeare, should have failed, six years after the event, to hear of that very memorable disgrace which had exiled him from Stratford, and was the very occasion of his first resorting to London; or that a leading company of players in the metropolis, *one of whom*, and a chief one, *was his own townsman*, should cheerfully adopt into their society, as an honoured partner, a young man yet flagrant from the lash of the executioner or the beadle?

---

[1] In a little memoir of Milton, which the author of this article drew up some years ago for a public society, and which is printed in an abridged shape, he took occasion to remark, that Dr Johnson, who was meanly anxious to revive this slander against Milton, as well as some others, had supposed Milton himself to have this flagellation in his mind, and indirectly to confess it, in one of his Latin poems, where, speaking of Cambridge, and declaring that he has no longer any pleasure in the thoughts of revisiting that university, he says,

> "Nec duri libet usque minas perferre magistri,
> Cæteraque ingenio non subeunda meo."

This last line the malicious critic would translate—"And other things insufferable to a man of my temper." But, as we then observed, *ingenium* is properly expressive of the *intellectual* constitution, whilst it is the *moral* constitution that suffers degradation from personal chastisement—the sense of honour, of personal dignity, of justice, &c. *Indoles* is the proper term for this latter idea; and in using the word *ingenium*, there cannot be a doubt that Milton alluded to the dry scholastic disputations, which were shocking and odious to his fine poetical genius. If, therefore, the vile story is still to be kept up in order to dishonour a great man, at any rate let it not in future be pretended that any countenance to such a slander can be drawn from the confessions of the poet himself.

This tale is fabulous, and rotten to its core; yet even this does less dishonour to Shakspeare's memory than the sequel attached to it. A sort of scurrilous rondeau, consisting of nine lines, so loathsome in its brutal stupidity, and so vulgar in its expression, that we shall not pollute our pages by transcribing it, has been imputed to Shakspeare ever since the days of the credulous Rowe. The total point of this idiot's drivel consists in calling Sir Thomas "an asse;" and well it justifies the poet's own remark, "Let there be gall enough in thy ink, no matter though thou write with a goose pen." Our own belief is, that these lines were a production of Charles II.'s reign, and applied to a Sir Thomas Lucy, not very far removed, if at all, from the age of him who first picked up the precious filth: the phrase "parliament *member*," we believe to be quite unknown in the colloquial use of Queen Elizabeth's reign.

But, that we may rid ourselves once and for ever of this outrageous calumny upon Shakspeare's memory, we shall pursue the story to its final stage. Even Malone has been thoughtless enough to accredit this closing chapter, which contains, in fact, such a superfetation of folly as the annals of human dulness do not exceed. Let us recapitulate the points of the story. A baronet, who has no deer and no park, is supposed to persecute a poet for stealing these aerial deer out of this aerial park, both lying in *nephelococcygia*. The poet sleeps upon this wrong for eighteen years; but at length, hearing that his persecutor is dead and buried, he conceives bloody thoughts of revenge. And this revenge he purposes to execute by picking a hole in his dead enemy's coat-of-arms. Is this coat-of-arms, then, Sir Thomas Lucy's? Why, no: Malone admits that it is not. For the poet, suddenly recollecting that this ridicule would settle upon the son of his enemy, selects another coat-of-arms, with which his dead enemy never had any connection, and he spends his thunder and lightning upon this irrelevant object; and, after all, the ridicule itself lies in a Welchman's mispronouncing one single heraldic term—a Welchman who mispronounces all words. The last act of the poet's malice recalls to us a sort of jest-book story of an Irishman, the vulgarity of which the reader will pardon in consideration of its relevancy. The Irishman having lost a pair of silk stockings, mentions to a friend that he has taken steps for recovering them by an advertisement, offering a reward to the finder. His friend objects that the costs of advertising, and the reward, would eat out the full value of the silk stockings. But to this the Irishman replies, with a knowing air, that he is not so green as to have overlooked *that;* and that, to keep down the reward, he had advertised the stockings as worsted. Not at all less flagrant is the bull ascribed to Shakspeare, when he is made to punish a dead man by personalities meant for his exclusive ear, through his coat-of-arms, but at the same time, with the express purpose of blunting and defeating the edge of his own scurrility, is made to substitute for the real arms some others which had no more relation to the dead enemy than they had to the poet himself. This is the very sublime of folly, beyond which human dotage cannot advance.

It is painful, indeed, and dishonourable to human nature, that whenever men of vulgar habits and of poor education wish to impress us with a feeling of respect for a man's talents, they are sure to cite, by way of evidence, some gross instance of malignity. Power, in their minds, is best illustrated by malice or by the infliction of pain. To this unwelcome fact we have some evidence in the wretched tale which we have just dismissed; and there is another of the same description to be found in all lives of Shakspeare, which we will expose to the contempt of the reader whilst we are in this field of discussion, that we may not afterwards have to resume so disgusting a subject.

This poet, who was a model of gracious benignity in his manners, and of whom, amidst our general ignorance, thus much is perfectly established, that the term *gentle* was almost as generally and by prescriptive right associated with his name as the affix of *venerable* with Bede, or *judicious* with Hooker, is alleged to have insulted a friend by an imaginary epitaph beginning "*Ten in the Hundred*," and supposing him to be damned, yet without wit enough (which surely the Stratford bellman could have furnished) for devising any, even fanciful, reason for such a supposition; upon which the comment of some foolish critic is, "The *sharpness of the satire* is said to have stung the man so much that he never forgave it." We have heard of the sting in the tail atoning for the brainless head; but in this doggerel the tail is surely as stingless as the head is brainless. For, 1*st*, *Ten in the Hundred* could be no reproach in Shakspeare's time, any more than to call a man *Three-and-a-half-per-cent.* in this present year 1838; except, indeed, amongst those foolish persons who built their morality upon the Jewish ceremonial law. Shakspeare himself took ten per cent. 2*dly*, It happens that John Combe, so far from being the object of the poet's scurrility, or viewing the poet as an object of implacable resentment, was a Stratford friend; that one of his family was affectionately remembered in Shakspeare's will by the bequest of his sword; and that John Combe himself recorded his perfect charity with Shakspeare by leaving him a legacy of L.5 sterling. And in this lies the key to the whole story. For, 3*dly*, the four lines were written and printed before Shakspeare was born. The name Combe is a common one; and some stupid fellow, who had seen the name in Shakspeare's will, and happened also to have seen the lines in a collection of epigrams, chose to connect the cases by attributing an identity to the two John Combes, though at war with chronology.

Finally, there is another specimen of doggerel attributed to Shakspeare, which is not equally unworthy of him, because not equally malignant, but otherwise equally below his intellect, no less than his scholarship; we mean the inscription on his grave-stone. This, as a sort of *siste viator* appeal to future sextons, is worthy of the grave-digger or the parish-clerk, who was probably its author. Or it may have been an antique formula, like the vulgar record of ownership in books—

Anthony Timothy Dolthead's book,
God give him grace therein to look.

Thus far the matter is of little importance; and it might have been supposed that malignity itself could hardly have imputed such trash to Shakspeare. But when we find, even in this short compass, scarcely wider than the posy of a ring, room found for traducing the poet's memory, it becomes important to say, that the leading sentiment, the horror expressed at any disturbance offered to his bones, is not one to which Shakspeare could have attached the slightest weight; far less could have outraged the sanctities of place and subject, by affixing to any sentiment whatever (and, according to the fiction of the case, his farewell sentiment) the sanction of a curse.

Filial veneration and piety towards the memory of this great man have led us into a digression that might have been unseasonable in any cause less weighty than one having for its object to deliver his honoured name from a load of the most brutal malignity. Never more, we hope and venture to believe, will any thoughtless biographer impute to Shakspeare the asinine doggerel with which the uncritical blundering of his earliest biographer has caused his name to be dishonoured. We now resume the thread of our biography. The stream of history is centuries in working itself clear of any calumny with which it has once been polluted.

Most readers will be aware of an old story, according to which Shakspeare gained his livelihood for some time after coming to London by holding the horses of those who rode to the play. This legend is as idle as any one of those which we have just exposed. No custom ever existed of riding on horseback to the play. Gentlemen, who rode valuable horses, would assuredly not expose them systematically to the injury of standing exposed to cold for two or even four hours; and persons of inferior rank would not ride on horseback in the town. Besides, had such a custom ever existed, stables (or sheds at least) would soon have arisen to meet the public wants; and in some of the dramatic sketches of the day, which noticed every fashion as it arose, this would not have been overlooked. The story is traced originally to Sir William Davenant. Betterton the actor, who professed to have received it from him, passed it onwards to Rowe, he to Pope, Pope to Bishop Newton the editor of Milton, and Newton to Dr Johnson. This pedigree of the fable, however, adds nothing to its credit, and multiplies the chances of some mistake. Another fable, not much less absurd, represents Shakspeare as having from the very first been borne upon the establishment of the theatre, and so far contradicts the other fable, but originally in the very humble character of *call-boy* or deputy prompter, whose business it was to summon each performer according to his order of coming upon the stage. This story, however, quite as much as the other, is irreconcileable with the discovery recently made by Mr Collier, that in 1589 Shakspeare was a shareholder in the important property of a principal London theatre. It seems destined that all the undoubted facts of Shakspeare's life should come to us through the channel of legal documents, which are better evidence even than imperial medals; whilst, on the other hand, all the fabulous anecdotes, not having an attorney's seal to them, seem to have been the fictions of the wonder-maker. The plain presumption from the record of Shakspeare's situation in 1589, coupled with the fact that his first arrival in London was possibly not until 1587, but according to the earliest account not before 1586, a space of time which leaves but little room for any remarkable changes of situation, seems to be, that, either in requital of services done to the players by the poet's family, or in consideration of money advanced by his father-in-law, or on account of Shakspeare's personal accomplishments as an actor, and as an adapter of dramatic works to the stage; for one of these reasons, or for all of them united, William Shakspeare, about the 23d year of his age, was adopted into the partnership of a respectable histrionic company, possessing a first-rate theatre in the metropolis. If 1586 were the year in which he came up to London, it seems probable enough that his immediate motive to that step was the increasing distress of his father; for in that year John Shakspeare resigned the office of alderman. There is, however, a bare possibility that Shakspeare might have gone to London about the time when he completed his twenty-first year, that is, in the spring of 1585, but not earlier. Nearly two years after the birth of his eldest daughter Susanna, his wife lay in for a second and a *last* time; but she then brought her husband twins, a son and a daughter. These children were baptized in February of the year 1585; so that Shakspeare's whole family of three children were born and baptized two months before he completed his majority. The twins were baptized by the names of Hamnet and Judith, those being the names of two amongst their sponsors, viz. Mr Sadler and his wife. Hamnet, which is a remarkable name in itself, becomes still more so from its resemblance to the immortal name of Hamlet[1] the Dane; it was, however, the real baptismal name of Mr Sadler, a friend of Shakspeare's, about fourteen years older than himself. Shakspeare's son must then have been most interesting to his heart, both as a twin child and as his only boy. He died in 1596, when he was about eleven years old. Both daughters survived their father; both married; both left issue, and thus gave a chance for continuing the succession from the great poet. But all the four grandchildren died without offspring.

Of Shakspeare personally, at least of Shakspeare the man, as distinguished from the author, there remains little more to record. Already in 1592, Greene, in his posthumous Groat's-worth of Wit, had expressed the earliest vocation of Shakspeare in the following sentence:—"There is an upstart crow, beautified with our feathers; in his own conceit the only *Shakscene* in a country!" This alludes to Shakspeare's office of re-casting, and even re-composing, dramatic works, so as to fit them for representation; and Master Greene, it is probable, had suffered in his self-estimation, or in his purse, by the alterations in some piece of his own which the duty of Shakspeare to the general interests of the theatre had obliged him to make. In 1591 it has been supposed that Shakspeare wrote his first drama, the Two Gentlemen of Verona; the least characteristically marked of all his plays, and, with the exception of Love's Labour's Lost, the least interesting.

From this year, 1591 to that of 1611, are just twenty years, within which space lie the whole dramatic creations of Shakspeare, averaging nearly one for every six months. In 1611 was written the Tempest, which is supposed to have been the last of all Shakspeare's works. Even on that account, as Mr Campbell feelingly observes, it has "a sort of sacredness;" and it is a most remarkable fact, and one calculated to make a man superstitious, that in this play the great enchanter Prospero, in whom, "*as if conscious*," says Mr Campbell, "*that this would be his last work*, the poet has been *inspired to typify himself* as a wise, potent, and *benevolent magician*," of whom, indeed, as of Shakspeare himself, it may be said, that "within that circle" (the circle of his own art) "none durst tread but he," solemnly and for ever renounces his mysterious functions, symbolically breaks his enchanter's wand, and declares that he will bury his books, his science, and his secrets

> Deeper than did ever plummet sound.

Nay, it is even ominous, that in this play, and from the voice of Prospero, issues that magnificent prophecy of the total destruction which should one day swallow up

---

[1] And singular enough it is, as well as interesting, that Shakspeare had so entirely superseded to his own ear and memory the name Hamnet by the dramatic name of Hamlet, that in writing his will, he actually mis-spells the name of his friend Sadler, and calls him Hamlet. His son, however, who should have familiarized the true name to his ear, had then been dead for twenty years.

> The solemn temples, the great globe itself,
> Yea all which it inherit.

And this prophecy is followed immediately by a most profound ejaculation, gathering into one pathetic abstraction the total philosophy of life:

> We are such stuff
> As dreams are made of; and our little life
> Is rounded by a sleep;

that is, in effect, our life is a little tract of feverish vigils, surrounded and islanded by a shoreless ocean of sleep—sleep before birth, sleep after death.

These remarkable passages were probably not undesigned; but if we suppose them to have been thrown off without conscious notice of their tendencies, then, according to the superstition of the ancient Grecians, they would have been regarded as prefiguring words, prompted by the secret genius that accompanies every man, such as insure along with them their own accomplishment. With or without intention, however, it is believed that Shakspeare wrote nothing more after this exquisite romantic drama. With respect to the remainder of his personal history, Dr Drake and others have supposed, that during the twenty years from 1591 to 1611, he visited Stratford often, and latterly once a year.

In 1589 he had possessed some share in a theatre; in 1596 he had a considerable share. Through Lord Southampton, as a surviving friend of Lord Essex, who was viewed as the martyr to his Scottish politics, there can be no doubt that Shakspeare had acquired the favour of James I.; and accordingly, on the 29th of May 1603, about two months after the king's accession to the throne of England, a patent was granted to the company of players who possessed the Globe theatre; in which patent Shakspeare's name stands second. This patent raised the company to the rank of his majesty's servants, whereas previously they are supposed to have been simply the servants of the Lord Chamberlain. Perhaps it was in grateful acknowledgment of this royal favour that Shakspeare afterwards, in 1606, paid that sublime compliment to the house of Stuart which is involved in the vision shown to Macbeth. This vision is managed with exquisite skill: it was impossible to display the whole series of princes from Macbeth to James I.; but he beholds the posterity of Banquo, one "gold-bound brow" succeeding to another, until he comes to an eighth apparition of a Scottish king,

> Who bears a glass
> Which shows him many more; and some he sees
> Who *twofold* balls and *treble* sceptres carry;

thus bringing down without tedium the long succession to the very person of James I. by the symbolic image of the two crowns united on one head.

About the beginning of the century Shakspeare had become rich enough to purchase the best house in Stratford, called *The Great House*, which name he altered to *New Place*; and in 1602 he bought 107 acres adjacent to this house for a sum (L.320) corresponding to about 1500 guineas of modern money. Malone thinks that he purchased the house as early as 1597; and it is certain that about that time he was able to assist his father in obtaining a renewed grant of arms from the Heralds' College, and therefore, of course, to re-establish his father's fortunes. Ten years of well-directed industry, viz. from 1591 to 1601, and the prosperity of the theatre in which he was a proprietor, had raised him to affluence; and after another ten years, improved with the same success, he was able to retire with an income of L.300, or (according to the customary computations) in modern money of L.1500, per annum. Shakspeare was in fact the first man of letters, Pope the second, and Sir Walter Scott the third, who, in Great Britain, has ever realized a large fortune by literature; or in Christendom, if we except Voltaire, and two dubious cases in Italy. The four or five latter years of his life Shakspeare passed in dignified ease, in profound meditation, we may be sure, and in universal respect, at his native town of Stratford; and there he died, on the 23d of April 1616.[1]

His daughter Susanna had been married on the 5th of June of the year 1607, to Dr John Hall,[2] a physician in Stratford. The doctor died in November 1635, aged sixty; his wife, at the age of sixty-six, on July 11, 1640. They had one child, a daughter, named Elizabeth, born in 1608, married April 22, 1626, to Thomas Nashe, Esq. left a widow in 1647, and subsequently remarried to Sir John Barnard; but this Lady Barnard, the sole grand-daughter of the poet, had no children by either marriage. The other daughter Judith, on February 10, 1616 (about ten weeks before her father's death) married Mr Thomas Quiney of Stratford, by whom she had three sons, Shakspeare, Richard, and Thomas. Judith was about thirty-one years old at the time of her marriage; and living just forty-six years afterwards, she died in February 1662, at the age of seventy-seven. Her three sons died without issue; and thus, in the direct lineal descent, it is certain that no representative has survived of this transcendent poet, the most august amongst created intellects.

After this review of Shakspeare's life, it becomes our duty to take a summary survey of his works, of his intellectual powers, and of his station in literature, a station which is now irrevocably settled, not so much (which happens in other cases) by a vast overbalance of favourable suffrages, as by acclamation; not so much by the *voices* of those who admire him up to the verge of idolatry, as by the *acts* of those who everywhere seek for his works among the primal necessities of life, demand them, and crave them as they do their daily bread; not so much by eulogy openly proclaiming itself, as by the silent homage recorded in the endless multiplication of what he has bequeathed us; not so much by his own compatriots, who, with regard to almost every other author,[3] compose the total amount of his

---

[1] "I have heard that Mr Shakspeare was a natural wit, without any art at all. Hee frequented the plays all his younger time, but in his elder days lived at Startford, and supplied the stage with two plays every year, and for itt had an allowance so large, that he spent at the rate of 1,000*l*. a-year, as I have heard. Shakespeare, Drayton, and Ben Jonson, had a merie meeting, and it seems drank too hard, for Shakespear died of a feavour there contracted." (Diary of the Rev. John Ward, A. M. Vicar of Stratford-upon-Avon, extending from 1648 to 1679, p. 183. Lond. 1839, 8vo.)

[2] It is naturally to be supposed that Dr Hall would attend the sick-bed of his father-in-law; and the discovery of this gentleman's medical diary promised some gratification to our curiosity as to the cause of Shakspeare's death. Unfortunately, it does not commence until the year 1617.

[3] An exception ought perhaps to be made for Sir Walter Scott and for Cervantes; but with regard to all other writers, Dante, suppose, or Ariosto amongst Italians, Camoens amongst those of Portugal, Schiller amongst Germans, however ably they may have been naturalized in foreign languages, as all of those here mentioned (excepting only Ariosto) have in one part of their works been most powerfully naturalized in English, it still remains true (and the very sale of the books is proof sufficient) that an alien author never does take root in the general sympathies out of his own country; he takes his station in libraries, he is read by the man of learned leisure, he is known and valued by the refined and the elegant, but he is not (what Shakspeare is for Germany and America) in any proper sense a *popular* favourite.

effective audience, as by the unanimous "all hail!" of intellectual Christendom; finally, not by the hasty partisanship of his own generation, nor by the biassed judgment of an age trained in the same modes of feeling and of thinking with himself, but by the solemn award of generation succeeding to generation, of one age correcting the obliquities or peculiarities of another; by the verdict of two hundred and thirty years, which have now elapsed since the very *latest* of his creations, or of two hundred and forty-seven years if we date from the earliest; a verdict which has been continually revived and re-opened, probed, searched, vexed, by criticism in every spirit, from the most genial and intelligent, down to the most malignant and scurrilously hostile which feeble heads and great ignorance could suggest when co-operating with impure hearts and narrow sensibilities; a verdict, in short, sustained and countersigned by a longer series of writers, many of them eminent for wit or learning, than were ever before congregated upon any inquest relating to any author, be he who he might, ancient[1] or modern, Pagan or Christian. It was a most witty saying with respect to a piratical and knavish publisher, who made a trade of insulting the memories of deceased authors by forged writings, that he was "among the new terrors of death." But in the gravest sense it may be affirmed of Shakspeare, that he is among the modern luxuries of life; that life, in fact, is a new thing, and one more to be coveted, since Shakspeare has extended the domains of human consciousness, and pushed its dark frontiers into regions not so much as dimly descried or even suspected before his time, far less illuminated (as now they are) by beauty and tropical luxuriance of life. For instance,—a single instance, indeed one which in itself is a world of new revelation,—the possible beauty of the female character had not been seen as in a dream before Shakspeare called into perfect life the radiant shapes of Desdemona, of Imogene, of Hermione, of Perdita, of Ophelia, of Miranda, and many others. The Una of Spenser, earlier by ten or fifteen years than most of these, was an idealized portrait of female innocence and virgin purity, but too shadowy and unreal for a dramatic reality. And as to the Grecian classics, let not the reader imagine for an instant that any prototype in this field of Shakspearian power can be looked for there. The *Antigone* and the *Electra* of the tragic poets are the two leading female characters that classical antiquity offers to our respect, but assuredly not to our impassioned love, as disciplined and exalted in the school of Shakspeare. They challenge our admiration, severe, and even stern, as impersonations of filial duty, cleaving to the steps of a desolate and afflicted old man; or of sisterly affection, maintaining the rights of a brother under circumstances of peril, of desertion, and consequently of perfect self-reliance. Iphigenia, again, though not dramatically coming before us in her own person, but according to the beautiful report of a spectator, presents us with a fine statuesque model of heroic fortitude, and of one whose young heart, even in the very agonies of her cruel immolation, refused to forget, by a single indecorous gesture, or so much as a moment's neglect of her own princely descent, and that she herself was "a lady in the land." These are fine marble groups, but they are not the warm breathing realities of Shakspeare; there is "no speculation" in their cold marble eyes; the breath of life is not in their nostrils; the fine pulses of womanly sensibilities are not throbbing in their bosoms. And besides this immeasurable difference between the cold moony reflexes of life, as exhibited by the power of Grecian art, and the true sunny life of Shakspeare, it must be observed that the Antigones, &c. of the antique put forward but one single trait of character, like the aloe with its single blossom: this solitary feature is presented to us as an abstraction, and as an insulated quality; whereas in Shakspeare all is presented in the *concrete*; that is to say, not brought forward in relief, as by some effort of an anatomical artist; but embodied and imbedded, so to speak, as by the force of a creative nature, in the complex system of a human life; a life in which all the elements move and play simultaneously, and with something more than mere simultaneity or co-existence, acting and re-acting each upon the other, nay, even acting by each other and through each other. In Shakspeare's characters is felt for ever a real *organic* life, where each is for the whole and in the whole, and where the whole is for each and in each. They only are real incarnations.

The Greek poets could not exhibit any approximations to *female* character, without violating the truth of Grecian life, and shocking the feelings of the audience. The drama with the Greeks, as with us, though much less than with us, was a picture of human life; and that which could not occur in life could not wisely be exhibited on the stage. Now, in ancient Greece, women were secluded from the society of men. The conventual sequestration of the γυναικωνίτις, or female apartment[2] of the house, and the Mahommedan consecration of its threshold against the ingress of males, had been transplanted from Asia into Greece thousands of years perhaps before either convents or Mahommed existed. Thus barred from all open social intercourse, women could not develope or express any character by word or action. Even to *have* a character, violated, to a Grecian mind, the ideal portrait of feminine excellence; whence, perhaps, partly the too generic, too little individualized, style of Grecian beauty. But prominently to *express* a character was impossible under the common tenor of Grecian life, unless when high tragical catastrophes transcended the decorums of that tenor, or for a brief interval raised the curtain which veiled it. Hence the subordinate part which women play upon the Greek stage in all but some half dozen cases. In the paramount tragedy on that stage, the model tragedy, the *Œdipus Tyrannus* of Sophocles, there is virtually no woman at all; for Jocasta is a party to the story merely as the dead Laius or the self-murdered Sphinx was a party, viz. by her contributions to the fatalities of the event, not by any thing she does or says spontaneously. In fact, the

Polyxena

---

[1] It will occur to many readers, that perhaps Homer may furnish the sole exception to this sweeping assertion: any *but* Homer is clearly and ludicrously below the level of the competition; but even Homer, "with his tail on" (as the Scottish Highlanders say of their chieftains when belted by their ceremonial retinues), musters nothing like the force which *already* follows Shakspeare; and be it remembered, that Homer sleeps and has long slept as a subject of criticism or commentary, while in Germany as well as England, and *now even in France*, the gathering of wits to the vast equipage of Shakspeare is advancing in an accelerated ratio. There is, in fact, a great delusion current upon this subject. Innumerable references to Homer, and brief critical remarks on this or that pretension of Homer, this or that scene, this or that passage, lie scattered over literature ancient and modern; but the express works dedicated to the separate service of Homer are, after all, not many. In Greek we have only the large Commentary of Eustathius, and the Scholia of Didymus, &c.; in French little or nothing before the prose translation of the seventeenth century, which Pope esteemed "elegant," and the skirmishings of Madame Dacier, La Motte, &c.; in English, besides the various translations and their prefaces (which, by the way, began as early as 1555), nothing of much importance until the elaborate preface of Pope to the Iliad, and his elaborate postscript to the Odyssey—nothing certainly before that, and very little indeed since that, except Wood's Essay on the Life and Genius of Homer. On the other hand, of the books written in illustration or investigation of Shakspeare, a very considerable library might be formed in England, and another in Germany.

[2] Apartment is here used, as the reader will observe, in its true and continental acceptation, as a division or *compartment* of a house including many rooms; a suite of chambers, but a suite which is partitioned off (as in palaces), not a single chamber; a sense so commonly and so erroneously given to this word in England.

Greek poet, if a wise poet, could not address himself genially to a task in which he must begin by shocking the sensibilities of his countrymen. And hence followed, not only the dearth of female characters in the Grecian drama, but also a second result still more favourable to the sense of a new power evolved by Shakspeare. Whenever the common law of Grecian life did give way, it was, as we have observed, to the suspending force of some great convulsion or tragical catastrophe. This for a moment (like an earthquake in a nunnery) would set at liberty even the timid, fluttering Grecian women, those doves of the dove-cot, and would call some of them into action. But which? Precisely those of energetic and masculine minds; the timid and feminine would but shrink the more from public gaze and from tumult. Thus it happened, that such female characters as *were* exhibited in Greece, could not but be the harsh and the severe. If a gentle Ismene appeared for a moment in contest with some energetic sister Antigone (and chiefly, perhaps, by way of drawing out the fiercer character of that sister), she was soon dismissed as unfit for scenical effect. So that not only were female characters few, but, moreover, of these few the majority were but repetitions of masculine qualities in female persons. Female agency being seldom summoned on the stage except when it had received a sort of special dispensation from its sexual character, by some terrific convulsions of the house or the city, naturally it assumed the style of action suited to these circumstances. And hence it arose, that not woman as she differed from man, but woman as she resembled man—woman, in short, seen under circumstances so dreadful as to abolish the effect of sexual distinction, was the woman of the Greek tragedy.[1] And hence generally arose for Shakspeare the wider field, and the more astonishing by its perfect novelty, when he first introduced female characters, not as mere varieties or echoes of masculine characters, a Medea or Clytemnestra, or a vindictive Hecuba, the mere tigress of the tragic tiger, but female characters that had the appropriate beauty of female nature; woman no longer grand, terrific, and repulsive, but woman "after her kind"—the other hemisphere of the dramatic world; woman running through the vast gamut of womanly loveliness; woman as emancipated, exalted, ennobled, under a new law of Christian morality; woman the sister and co-equal of man, no longer his slave, his prisoner, and sometimes his rebel. "It is a far cry to Loch Awe;" and from the Athenian stage to the stage of Shakspeare, it may be said, is a prodigious interval. True; but prodigious as it is, there is really nothing between them. The Roman stage, at least the tragic stage, as is well known, was put out, as by an extinguisher, by the cruel amphitheatre, just as a candle is made pale and ridiculous by daylight. Those who were fresh from the real murders of the bloody amphitheatre regarded with contempt the mimic murders of the stage. Stimulation too coarse and too intense had its usual effect in making the sensibilities callous. Christian emperors arose at length, who abolished the amphitheatre in its bloodier features. But by that time the genius of the tragic muse had long slept the sleep of death. And that muse had no resurrection until the age of Shakspeare. So that, notwithstanding a gulf of nineteen centuries and upwards separates Shakspeare from Euripides, the last of the surviving Greek tragedians, the one is still the nearest successor of the other, just as Connaught and the islands in Clew Bay are next neighbours to America, although three thousand watery columns, each of a cubic mile in dimensions, divide them from each other.

A second reason, which lends an emphasis of novelty and effective power to Shakspeare's female world, is a peculiar fact of contrast which exists between that and his corresponding world of men. Let us explain. The purpose and the intention of the Grecian stage was not primarily to develope human *character*, whether in men or in women; human *fates* were its object; great tragic situations under the mighty control of a vast cloudy destiny, dimly descried at intervals, and brooding over human life by mysterious agencies, and for mysterious ends. Man, no longer the representative of an august *will*, man the passion-puppet of fate, could not with any effect display what we call a character, which is a distinction between man and man, emanating originally from the will, and expressing its determinations, moving under the large variety of human impulses. The will is the central pivot of character; and this was obliterated, thwarted, cancelled, by the dark fatalism which brooded over the Grecian stage. That explanation will sufficiently clear up the reason why marked or complex variety of character was slighted by the great principles of the Greek tragedy. And every scholar who has studied that grand drama of Greece with feeling,—that drama, so magnificent, so regal, so stately,—and who has thoughtfully investigated its principles, and its difference from the English drama, will acknowledge that powerful and elaborate character, character, for instance, that could employ the fiftieth part of that profound analysis which has been applied to Hamlet, to Falstaff, to Lear, to Othello, and applied by Mrs Jamieson so admirably to the full development of the Shakspearian heroines, would have been as much wasted, nay, would have been defeated, and interrupted the blind agencies of fate, just in the same way as it would injure the shadowy grandeur of a ghost to individualize it too much. Milton's angels are slightly touched, superficially touched, with differences of character; but they are such differences, so simple and general, as are just sufficient to rescue them from the reproach applied to Virgil's "*fortemque Gyan, fortemque Cloanthem*;" just sufficient to make them knowable apart. Pliny speaks of painters who painted in one or two colours; and, as respects the angelic characters, Milton does so; he is *monochromatic*. So, and for reasons resting upon the same ultimate philosophy, were the mighty architects of the Greek tragedy. They also were monochromatic; they also, as to the characters of their persons, painted in one colour. And so far there might have been the same novelty in Shakspeare's men as in his women. There *might* have been; but the reason why there is *not*, must be sought in the fact, that History, the muse of History, had there even been no such muse as Melpomene, would have forced us into an acquaintance with human character. History, as the representative of actual life, of real man, gives us powerful delineations of character in its chief agents, that is, in men; and therefore it is that Shakspeare, the absolute creator of female character, was but the mightiest of all painters with regard to male character. Take a single instance. The Antony of Shakspeare, immortal for its execution, is found, after all, as regards the primary conception, in history: Shakspeare's delineation is but the expansion of the germ already pre-existing, by way of scattered fragments, in Cicero's Philippics, in Cicero's Letters, in Appian, &c. But Cleopatra, equally fine, is a pure creation of art: the situation and the scenic circumstances belong to history, but the character belongs to Shakspeare.

In the great world therefore of woman, as the interpreter of the shifting phases and the lunar varieties of that mighty changeable planet, that lovely satellite of man, Shakspeare stands not the first only, not the original only, but is yet the sole authentic oracle of truth. Woman, therefore, the beauty of the female mind, *this* is one great field of his power. The supernatural world, the world of apparitions, *that* is another: for reasons which it would be easy to give, reasons emanating from the gross mythology of the ancients, no Grecian,[1] no Roman, could have conceived a ghost. That shadowy conception, the protesting apparition, the awful projection of the human conscience, belongs to the Christian mind: and in all Christendom, who, let us ask, who, who but Shakspeare has found the power for effectually working this mysterious mode of being? In summoning back to earth "the majesty of buried Denmark," how like an awful necromancer does Shakspeare appear! All the pomps and grandeurs which religion, which the grave, which the popular superstition had gathered about the subject of apparitions, are here converted to his purpose, and bend to one awful effect. The wormy grave brought into antagonism with the scenting of the early dawn; the trumpet of resurrection suggested, and again as an antagonist idea to the crowing of the cock (a bird ennobled in the Christian mythus by the part he is made to play at the Crucifixion); its starting "as a guilty thing" placed in opposition to its majestic expression of offended dignity when struck at by the partisans of the sentinels; its awful allusions to the secrets of its prison-house; its ubiquity, contrasted with its local presence; its aerial substance, yet clothed in palpable armour; the heart-shaking solemnity of its language, and the appropriate scenery of its haunt, viz. the ramparts of a capital fortress, with no witnesses but a few gentlemen mounting guard at the dead of night,—what a mist, what a *mirage* of vapour, is here accumulated, through which the dreadful being in the centre looms upon us in far larger proportions than could have happened had it been insulated and left naked of this circumstantial pomp! In the *Tempest*, again, what new modes of life, preternatural, yet far as the poles from the spiritualities of religion. Ariel in antithesis to Caliban! What is most ethereal to what is most animal! A phantom of air, an abstraction of the dawn and of vesper sun-lights, a bodiless sylph on the one hand; on the other a gross carnal monster, like the Miltonic Asmodai, "the fleshliest incubus" among the fiends, and yet so far ennobled into interest by his intellectual power, and by the grandeur of misanthropy![2] In the *Midsummer-Night's Dream*, again, we have the old traditional fairy, a lovely mode of preternatural life, remodified by Shakspeare's eternal talisman. Oberon and Titania remind us at first glance of Ariel: they approach, but how far they recede: they are like—"like, but, oh, how different!" And in no other exhibition of this dreamy population of the moonlight forests and forest-lawns, are the circumstantial proprieties of fairy life so exquisitely imagined, sustained, or expressed. The dialogue between Oberon and Titania is, of itself, and taken separately from its connection, one of the most delightful poetic scenes that literature affords. The witches in Macbeth are another variety of supernatural life, in which Shakspeare's power to enchant and to disenchant are alike portentous. The circumstances of the blasted heath, the army at a distance, the withered attire of the mysterious hags, and the choral litanies of their fiendish Sabbath, are as finely imagined in their kind as those which herald and which surround the ghost in Hamlet. There we see the *positive* of Shakspeare's superior power. But now turn and look to the *negative*. At a time when the trials of witches, the royal book on demonology, and popular superstition (all so far useful, as they prepared a basis of undoubting faith for the poet's serious use of such agencies) had degraded and polluted the ideas of these mysterious beings by many mean associations, Shakspeare does not fear to employ them in high tragedy (a tragedy moreover which, though not the very greatest of his efforts as an intellectual whole, nor as a struggle of passion, is *among* the greatest in any view, and positively *the* greatest for scenical grandeur, and in that respect makes the nearest approach of all English tragedies to the Grecian model); he does not fear to introduce, for the same appalling effect as that for which Æschylus introduced the Eumenides, a triad of old women, concerning whom an English wit has remarked this grotesque peculiarity in the popular creed of that day,—that although potent over winds and storms, in league with powers of darkness, they yet stood in awe of the constable,—yet relying on his own supreme power to disenchant as well as to enchant, to create and to uncreate, he mixes these women and their dark machineries with the power of armies, with the agencies of kings, and the fortunes of martial kingdoms. Such was the sovereignty of this poet, so mighty its compass!

---

[1] And hence, by parity of reason, under the opposite circumstances, under the circumstances which, instead of abolishing, most emphatically drew forth the sexual distinctions, viz. in the *comic* aspects of social intercourse, the reason that we see no women on the Greek stage; the Greek comedy, unless when it affects the extravagant fun of farce, rejects women.

A third fund of Shakspeare's peculiar power lies in his teeming fertility of fine thoughts and sentiments. From his works alone might be gathered a golden bead-roll of thoughts the deepest, subtilest, most pathetic, and yet most catholic and universally intelligible; the most characteristic, also, and appropriate to the particular person, the situation, and the case, yet, at the same time, applicable to the circumstances of every human being, under all the accidents of life, and all vicissitudes of fortune. But this subject offers so vast a field of observation, it being so eminently the prerogative of Shakspeare to have thought more finely and more extensively than all other poets combined, that we cannot wrong the dignity of such a theme by doing more, in our narrow limits, than simply noticing it as one of the emblazonries upon Shakspeare's shield.

Fourthly, we shall indicate (and, as in the last case, *barely* indicate, without attempting in so vast a field to offer any inadequate illustrations) one mode of Shakspeare's dramatic excellence which hitherto has not attracted any special or separate notice. We allude to the forms of life, and natural human passion, as apparent in the structure of his dialogue. Among the many defects and infirmities of the

---

[1] It may be thought, however, by some readers, that Æschylus, in his fine phantom of Darius, has approached the English ghost. As a foreign ghost, we would wish (and we are sure that our excellent readers would wish) to show every courtesy and attention to this apparition of Darius. It has the advantage of being royal, an advantage which it shares with the ghost of the royal Dane. Yet how different, how removed by a total world, from that or any of Shakspeare's ghosts! Take that of Banquo, for instance: how shadowy, how unreal, yet how real! Darius is a mere state ghost—a diplomatic ghost. But Banquo—he exists only for Macbeth; the guests do not see him, yet how solemn, how real, how heart-searching he is.

[2] Caliban has not yet been thoroughly fathomed. For all Shakspeare's great creations are like works of nature, subjects of unexhaustible study. It was this character of whom Charles I. and some of his ministers expressed such fervent admiration; and, among other circumstances, most justly they admired the new language almost with which he is endowed, for the purpose of expressing his fiendish and yet carnal thoughts of hatred to his master. Caliban is evidently not meant for scorn, but for abomination mixed with fear and partial respect. He is purposely brought into contrast with the drunken Trinculo and Stephano, with an advantageous result. He is much more intellectual than either, uses a more elevated language, not disfigured by vulgarisms, and is not liable to the low passion for plunder as they are. He is mortal, doubtless, as his "dam" (for Shakspeare will not call her mother) Sycorax. But he inherits from her such qualities of power as a witch could be supposed to bequeath. He trembles indeed before Prospero; but that is, as we are to understand, through the moral superiority of Prospero in Christian wisdom; for when he finds himself in the presence of dissolute and unprincipled men, he rises at once into the dignity of intellectual power.

French and of the Italian drama, indeed we may say of the Greek, the dialogue proceeds always by independent speeches, replying indeed to each other, but never modified in its several openings by the momentary effect of its several terminal forms immediately preceding. Now, in Shakspeare, who first set an example of that most important innovation, in all his impassioned dialogues, each reply or rejoinder seems the mere rebound of the previous speech. Every form of natural interruption, breaking through the restraints of ceremony under the impulses of tempestuous passion; every form of hasty interrogative, ardent reiteration when a question has been evaded; every form of scornful repetition of the hostile words; every impatient continuation of the hostile statement; in short, all modes and formulæ by which anger, hurry, fretfulness, scorn, impatience, or excitement under any movement whatever, can disturb or modify or dislocate the formal bookish style of commencement,—these are as rife in Shakspeare's dialogue as in life itself; and how much vivacity, how profound a verisimilitude, they add to the scenic effect as an imitation of human passion and real life, we need not say. A volume might be written illustrating the vast varieties of Shakspeare's art and power in this one field of improvement; another volume might be dedicated to the exposure of the lifeless and unnatural result from the opposite practice in the foreign stages of France and Italy. And we may truly say, that were Shakspeare distinguished from them by this single feature of nature and propriety, he would on that account alone have merited a great immortality. (w. w. w.)

The dramatic works of Shakspeare generally acknowledged to be genuine consist of thirty-five pieces. The following is the chronological order in which they are supposed to have been written, according to Mr Malone as given in his second edition of Shakspeare, and by Mr George Chalmers in his Supplemental Apology for the Believers in the Shakspeare Papers.

	Chalmers.	Malone.
1. The Comedy of Errors,	1591	1592
2. Love's Labour's Lost,	1592	1594
3. Romeo and Juliet,	1592	1596
4. Henry VI. the First Part,	1593	1589
5. Henry VI. the Second Part,	1595	1591
6. Henry VI. the Third Part,	1595	1591
7. The Two Gentlemen of Verona,	1595	1591
8. Richard III.	1596	1593
9. Richard II.	1596	1593
10. The Merry Wives of Windsor,	1596	1601
11. Henry IV. the First Part,	1597	1597
12. Henry IV. the Second Part,	1597	1599
13. Henry V.	1597	1599
14. The Merchant of Venice,	1597	1594
15. Hamlet,	1598	1600
16. King John,	1598	1596
17. A Midsummer-Night's Dream,	1598	1594
18. The Taming of the Shrew,	1599	1596
19. All's Well that Ends Well,	1599	1606
20. Much Ado about Nothing,	1599	1600
21. As You Like It,	1602	1599
22. Troilus and Cressida,	1610	1602
23. Timon of Athens,	1611	1610
24. The Winter's Tale,	1601	1611
25. Measure for Measure,	1604	1603
26. King Lear,	1605	1605
27. Cymbeline,	1606	1609
28. Macbeth,	1606	1606
29. Julius Cæsar,	1607	1607
30. Antony and Cleopatra,	1608	1608
31. Coriolanus,	1619	1610
32. The Tempest,	1613	1611
33. The Twelfth Night,	1613	1607
34. Henry VIII.	1613	1603
35. Othello,	1614	1604

Pericles and Titus Andronicus, although inserted in all the late editions of Shakspeare's Plays, are omitted in the above list, both by Malone and Chalmers, as not being Shakspeare's.

The first edition of the Works was published in 1623, in a folio volume entitled Mr William Shakspeare's Comedies, Histories, and Tragedies. The second edition was published in 1632, the third in 1664, and the fourth in 1685, all in folio; but the edition of 1623 is considered the most authentic. Rowe published an edition in seven vols. 8vo in 1709. Editions were published by Pope, in six vols. 4to, in 1725; by Warburton, in eight vols. 8vo, in 1747; by Dr Johnson, in eight vols. 8vo, in 1765; by Stevens, in four vols. 8vo, in 1766; by Malone, in ten vols. 8vo, in 1789; by Alexander Chalmers, in nine vols. 8vo, in 1811; by Johnson and Stevens, revised by Isaac Reed, in twenty-one vols. 8vo, in 1813; and the Plays and Poems, with notes by Malone, were edited by James Boswell, and published in twenty-one vols. 8vo, in 1821. Besides these, numerous editions have been published from time to time.

SHALLOP, Shalloop, or Sloop, is a light vessel, with only a small main-mast and fore-mast, and lug-sails, to haul up and let down on occasion. Shallops are commonly good sailers, and are therefore often used as tenders upon men-of-war.

SHAMANS are wizards or conjurers, in high repute among several idolatrous nations inhabiting different parts of Russia. By their enchantments they pretend to cure diseases, to divert misfortunes, and to foretell futurity. They are great observers of dreams, by the interpretation of which they judge of good or bad fortune. They pretend likewise to chiromancy, and to foretell a man's good or ill success by the lines of his hand. By these and such like means they have a very great ascendency over the understandings, and a great influence on the conduct, of those people.

SHAMBLES, among miners, a sort of niches or landing places, left at such distances in the adits of the mines, that the shovel-men may conveniently throw up the ore from shamble to shamble, till it comes to the top of the mine.

SHAMLY, a town of Hindustan, in the province of Delhi. It is about two miles in circumference, and contains many handsome houses, with a large bazaar, and the remains of a mint. The streets intersect each other at right angles, and have separate gates, which are shut at night. It is sixty miles north by east from Delhi. Long. 77. 10. E. Lat. 29. 33. N.

SHAMOIS, or Chamois, a kind of leather, either dressed in oil or tanned, much esteemed for its softness and pliancy. It is prepared from the skin of the chamois, or shamois, a kind of wild goat, called also isard, inhabiting the mountains of Dauphiné, Savoy, Piedmont, and the Pyrenees. Besides the softness and warmth of the leather, it has the faculty of bearing soap without damage, which renders it very useful on many accounts.

SHANAVAZ, a town of the Afghan territories, in the province of Mooltan, seventy-eight miles east from the city of Mooltan. Long. 72. 39. E. Lat. 30. 41. N.

SHANDORAH, a town of Hindustan, in the province of Delhi, 120 miles from the city of Delhi. Long. 77. E. Lat. 30. 26. N.

SHANK'S Island, in the South Pacific Ocean, about annon || harp, ames.

fifteen miles from east to west, and eighteen from north to south, discovered in 1802. Long. 163. E. Lat. 28. S.

SHANNON, the largest river in Ireland, and one of the finest in the British dominions, not only on account of its running two hundred miles, but also of its great depth in most places, and the gentleness of its current, by which it might be made exceedingly serviceable to the improvement of the country, the communication of its inhabitants, and consequently the promoting of inland trade through the greater part of its long course. But the peculiar prerogative of the Shannon is its situation, running from north to south, and separating the province of Connaught from Leinster and Munster, and of consequence dividing the greater part of Ireland into that which lies on the east and west of the river; watering in its passage the valuable counties of Leitrim, Roscommon, Galway, and Clare; the small shire of Longford, King's County, and Meath in Leinster, Tipperary, Limerick, and Kerry in Munster; visiting ten counties in its passage, and having on its banks Leitrim, Jamestown, Lanesborough, Athlone, Clonfert, Killaloe, and Limerick. It at last joins its waters to the sea, being navigable all this way for the largest vessels.

SHAPOORAH, a town of Hindustan, in the province of Ajmeer and district of Harowty. It is a large and well-built town, surrounded by a strong wall of stone and a ditch. It is sixty-five miles south by east from the city of Ajmeer. Long. 75. 9. E. Lat. 25. 43. N.

SHAPOUR, an ancient city of Persia, which existed prior to the era of Alexander, but of which the former magnificence is now only marked by masses of ruins. It is situated immediately under a range of mountains, on the banks of a small but rapid river, amid rocks and precipices, many of which are decorated with sculpture.

SHARP, James, archbishop of St Andrews, was born of a good family in Banffshire in the year 1618. He devoted himself early to the church, and was educated for that purpose in the university of Aberdeen. When the solemn league and covenant was framed in 1638, the learned men in that seminary, and young Sharp in particular, declared themselves decidedly against it. To avoid the insults and indignities to which he was subjected in consequence of this conduct, he retired to England, where he contracted an acquaintance with some of the most celebrated divines in that country.

At the commencement of the civil wars he returned to Scotland. During his journey thither, he accidentally met with Lord Oxenford, who was so charmed with his conversation that he invited him to his house. While he resided with that nobleman, he became known to the Earl of Rothes, who procured him a professorship at St Andrews. By the interest of the Earl of Crawford, he was soon afterwards appointed minister of Crail, where he conducted himself, it is said, in an exemplary manner.

Sharp had always inclined to the cause of royalty, and had for some time kept up a correspondence with his exiled prince. After this he began to declare himself more openly, and seems to have enjoyed a great share of the confidence of Monk, who was at that time planning the restoration of Charles II. When that general marched to London, the presbyterians sent Sharp to attend him, in order to support their interests. At the request of General Monk and the chief presbyterians in Scotland, Mr Sharp was sent over to the king at Breda, to procure from him, if possible, the establishment of presbytery. On his return, he assured his friends that "he had found the king very affectionate to Scotland, and resolved not to wrong the settled government of the church; but he apprehended they were mistaken who went about to establish the presbyterian government."

Charles was soon afterwards restored without any terms. All the laws passed in Scotland since the year 1633 were repealed; the king and his ministers resolved at all hazards to restore prelacy. Mr Sharp, who had been commissioned by the Scotch presbyterians to manage their interests with the king, was prevailed upon to abandon the party; and as a reward for his compliance, he was made archbishop of St Andrews. This conduct rendered him very odious in Scotland. He was accused of treachery and perfidy, and reproached by his old friends as a traitor and renegade. The absurd and wanton cruelties which were afterwards committed, and which were imputed in a great measure to the archbishop, rendered him still more detested. Nor is it probable that these accusations were without foundation. The very circumstance of his having formerly been of the presbyterian party would induce him, after forsaking them, to treat them with severity. Besides, it is certain, that when, after the rout at Pentland Hills, he received an order from the king to stop the executions, he kept it for some time before he produced it to the council.

Sharp.

There was one Mitchell, a preacher, and a desperate fanatic, who had formed the design of taking vengeance for these cruelties by assassinating the archbishop. He fired a pistol at him as he was sitting in his coach; but the bishop of Orkney, lifting up his hand at the moment, intercepted the ball. Though this happened in the midst of Edinburgh, the primate was so much detested, that nobody stopped the assassin, who, having walked leisurely home, and thrown off his disguise, returned, and mixed unsuspected with the crowd. Some years afterwards, the archbishop observing a man eyeing him with keenness, suspected that he was the assassin, and ordered him to be brought before him. It was Mitchell. Two loaded pistols were found in his pocket. The primate offered him a pardon if he would confess the crime. The man complied; but Sharp, regardless of his promise, conducted him to the council. The council also gave him a solemn promise of pardon if he would confess his guilt, and discover his accomplices. They were much disappointed to hear that only one man was privy to his purpose, who was since dead. Mitchell was then brought before a court of justice, and ordered to make a third confession, which he refused. He was imprisoned for several years, and then tried. His own confession was urged against him. It was in vain for him to plead the illegality of that evidence, and to appeal to the promise of pardon previously given. The council took an oath that they had given no such promise, and Mitchell was condemned. Lauderdale, who at that time governed Scotland, would have pardoned him, but the primate insisted on his execution, observing, that if assassins were permitted to go unpunished, his life must be continually in danger. Mitchell was accordingly executed.

Sharp had a servant, one Carmichael, who by his cruelty had rendered himself particularly odious to the zealots. Nine men formed the resolution of waylaying him in Magus Moor, about three miles from St Andrews. While they were waiting for this man, the primate himself appeared, with very few attendants. This they looked upon as a declaration of heaven in their favour; and calling out, "the Lord has delivered him into our hands," they ran up to the carriage. They fired at him without effect; a circumstance which was afterwards imputed to magic. They then despatched him with their swords, regardless of the tears and entreaties of his daughter, who accompanied him.

Thus fell Archbishop Sharp, whose memory is even at present detested by the common people of Scotland. His abilities were certainly good, and in the early part of his life he appears with honour and dignity. But his conduct afterwards was too cruel and insincere to merit approbation. His treatment of Mitchell was mean and vindictive. How far he contributed to the measures adopted against the presbyterians is not certain. They were equally cruel and impolitic; nor did their effects cease with the measures themselves. The unheard-of cruelties exercised by the ministers of Charles II. against the adherents of the covenant, raised such a flame of enthusiasm and bigotry as is not yet entirely extinguished.

Sharp, *Dr John*, Archbishop of York, was descended from the Sharps of Little Norton, a family of Bradford Dale in Yorkshire; and was son of an eminent tradesman of Bradford, where he was born in 1644. He was educated at Cambridge, and in 1667 entered into orders. The same year he became domestic chaplain to Sir Heneage Finch, then attorney-general. In 1672 he was collated to the archdeaconry of Berkshire. In 1675 he was installed a prebendary in the cathedral church of Norwich; and the year following was instituted into the rectory of St Bartholomew, near the Royal Exchange, London. In 1681 he was, by the interest of his patron Sir Heneage Finch, then lord high chancellor of England, made dean of Norwich, but in 1686 was suspended for taking occasion, in some of his sermons, to vindicate the doctrine of the Church of England in opposition to Popery. In 1688 he was sworn chaplain to James II. being then probably restored after his suspension; for it is certain that he was chaplain to Charles II. and attended as a court chaplain at the coronation of James II. In 1689 he was declared dean of Canterbury, but never could be persuaded to fill up any of the vacancies made by the deprived bishops. Upon the death of Dr Lamplugh, he was promoted to the see of York. In 1702 he preached the sermon at the coronation of Queen Anne; and the same year he was sworn of the privy council, and made lord almoner to her majesty. He died at Bath in 1713, and was interred in the cathedral of York, where a monument was erected to his memory. His sermons were collected after his death, and published in seven vols. 8vo.

Sharp, *Abraham*, an eminent English mathematician and astronomer, was born at Little Horton, near Bradford, in the year 1651. He was put as apprentice to a merchant at Manchester; but so strongly was he inclined to the study of mathematics, that he soon found his situation both irksome and disagreeable. By the mutual consent, therefore, of his master and himself, he quitted the business of a merchant. He then removed to Liverpool, where he devoted himself wholly to mathematical studies, and where, for a subsistence, he taught writing and accounts.

Soon after this, a merchant from London, in whose house the celebrated Flamsteed then lodged, engaged Sharp to be his book-keeper. With this eminent astronomer he soon contracted an intimate friendship, and by his recommendation he obtained a more profitable employment in the dock-yard of Chatham, where he continued till his friend and patron called him to his assistance. Mr Sharp was chiefly employed in the construction of the mural arch, which he finished in the course of fourteen months, so entirely to the satisfaction of Flamsteed, that he spoke of him in terms of the highest praise. In the opinion of Smeaton, this was the first good instrument of the kind, and Sharp the first artist who cut delicate divisions on astronomical instruments. When this instrument was constructed, Sharp was but twenty-five and Flamsteed thirty years of age. Mr Sharp assisted his friend in making a catalogue of nearly three thousand fixed stars, with their longitudes and magnitudes, their right ascensions and polar distances, with the variations of the same while they change their longitude by one degree.

But, from the fatigue of constantly observing the stars by night in a cold thin air, added to a weakly constitution, his health was much impaired. For the recovery of it he requested leave to retire to his house at Horton, where, as soon as he felt himself recovering, he began to fit up an observatory of his own; and the telescopes he made use of were all of his own construction, and the lenses ground and adjusted with his own hands.

It was about this time that he assisted Flamsteed in calculating most of the tables in the second volume of his *Historia Cœlestis*, as appears by their letters, to be seen in the hands of Sharp's friends at Horton. The mathematician, says Dr Hutton, meets with something extraordinary in Sharp's elaborate treatise of Geometry Improved; by a large and accurate table of segments of circles, its construction and various uses in the solution of several difficult problems, with compendious tables for finding a true proportional part; and their use in these or any other tables exemplified in making logarithms, or their natural numbers, to sixty places of figures, there being a table of them for all primes to 1100, true to sixty-one figures. His concise treatise of Polyedra, or solid bodies of many bases, both of the regular ones and others, to which are added twelve new ones, with various methods of forming them, and their exact dimensions in surds and in numbers; illustrated with a variety of copperplates, neatly engraved by his own hands. Indeed few of the mathematical instrument makers could exceed him in exactly graduating or neatly engraving mathematical or astronomical instruments. He possessed a remarkably clear head for contriving, and an extraordinary hand for executing, any thing, not only in mechanics, but likewise in drawing, writing, and making the most beautiful figures, in all his calculations and constructions.

The quadrature of the circle was undertaken by him for his own amusement, in the year 1699, deduced from two different series, by which the truth of it was proved to seventy-two places of figures, as may be seen in Sherwin's Tables of Logarithms. In the same book may likewise be seen his ingenious improvements on the making of logarithms, and the constructing of the natural sines, tangents, and secants.

Mr Sharp kept up a correspondence with most of the eminent mathematicians and astronomers of his time, as Flamsteed, Newton, Halley, Wallis, Hodgson, the answers to whose letters are all written on the backs or empty spaces of the letters he received, in a short hand of his own invention. Being one of the most accurate and indefatigable computers who ever existed, he was many years the common resource for Flamsteed, Sir Jonas Moor, Halley, and others, in all sorts of troublesome and delicate calculations.

Sharp was never married, and spent his time as a hermit. He was of a middle stature, very thin, of a weakly constitution, and remarkably feeble during the last three or four years before his death, which happened on the 18th of July 1742, in the ninety-first year of his age.

He was very irregular as to his meals, and uncommonly sparing in his diet. A little square hole, resembling a window, formed a communication between the room where he usually studied, and another where a servant could enter; and before this hole he had contrived a sliding board. It often happened, that the breakfast, dinner, and supper, have remained untouched, when the servant had gone to remove what was left, so deeply was he engaged in calculations.

Sharp, in *Music*. See Music.

SHASTER or Shastrah, the name of a sacred book, in high estimation among the idolaters of Hindustan, containing all the dogmas of the religion of the Brahmins, and all the ceremonies of their worship, and serving as a commentary on the Vedam.

The term *Shaster* denotes science or system; and is applied to other works of astronomy and philosophy, which have no relation to the religion of the Indians. None but the Brahmins and rajahs of India are allowed to read the Vedam; the priests of the Banians, called Shuderis, may read the Shaster; and the people in general are allowed to read only the Paran or Pouran, which is a commentary on the Shaster.

The Shaster is divided into three parts, the first containing the moral law of the Indians; the second, the rites and ceremonies of their religion; and the third, the distribution of the people into tribes or classes, with the duties pertaining to each class.

The principal precepts of morality, contained in the first part of the Shaster, are the following. That no animal be killed, because the Indians attribute souls to brute animals as well as to mankind; that they neither hear nor speak evil, nor drink wine, nor eat flesh, nor touch any thing that is unclean; that they observe the feasts, prayers, and washings which their law prescribes; that they tell no lies, nor be guilty of deceit in trade; that they neither oppress nor offer violence to one another; that they celebrate the solemn feasts and fasts, and appropriate certain hours of ordinary sleep to cultivate a disposition for prayer; and that they do not steal or defraud one another.

The ceremonies, contained in the second part of the Shaster, are these. That they wash often in the rivers, thereby obtaining the pardon of their sins; that they mark their forehead with red, in token of their relation to the Deity; that they present offerings and prayers under certain trees, set apart for this purpose; that they pray in the temples, make oblations to their pagodas or idols, sing hymns, and make processions; that they make pilgrimages to distant rivers, and especially to the Ganges, there to wash themselves and make offerings; that they make vows to particular saints, according to their respective departments; that they render homage to the Deity at the first sight of the sun; that they pay their respect to the sun and moon, which are the two eyes of the Deity; and that they treat with particular veneration those animals that are deemed more pure than others, because the souls of men have transmigrated into these animals.

The third part of the Shaster records the distribution of the people into four classes; the first being that of the Brahmins or priests, appointed to instruct the people; the second, that of the kutteris or nobles, who are the magistrates; the third, that of the shudderis or merchants; and the fourth, that of the mechanics. Each person is required to remain in the class in which he was born, and to pursue the occupation assigned to him by the Shaster. According to the Brahmins, the Shaster was imparted by God himself to Brahma, and by him to the Brahmins, who communicated the contents of it to the people.

Modern writers have given us very different accounts of the antiquity and importance of the Shaster. Mr Holwell, who had made considerable progress in the translation of this book, apprehends that the mythology as well as the cosmogony of the Egyptians, Greeks, and Romans, was borrowed from the doctrines of the Brahmins contained in it, even to the copying of the exteriors of worship, and the distribution of their idols, though grossly mutilated and adulterated. With respect to the Vedam and Shaster, or scriptures, of the Gentoos, this writer informs us, that Vedam, in the Malabar language, signifies the same as Shaster in the Sanscrit; and that the first book is followed by the Gentoos of the Malabar and Coromandel coasts, and also of the island of Ceylon. The Shaster is followed by the Gentoos of the provinces of Bengal, and by all the Gentoos of the rest of India, commonly called India Proper, along the course of the rivers Ganges and Jumna, to the Indus. Both these books, he says, contain the institutes of their respective religion and worship, as well as the history of their ancient rajahs and princes, often couched under allegory and fable. Their antiquity is contended for by the partisans of each; but he thinks that the similitude of their names, idols, and great part of their worship, leaves little room to doubt, nay plainly evinces, that both these scriptures were originally one. He adds, if we compare the great purity and chaste manners of the Shaster with the great absurdities and impurities of the Vedam, we need not hesitate to pronounce the latter a corruption of the former.

Shaster.

With regard to the high original of these scriptures, the account of the Brahmins is as follows. Brahma, or the Mighty Spirit, about 4866 years ago, assumed the form of man, and the government of Hindustan. He translated the divine law, designed for the restoration of mankind, who had offended in a pre-existent state, and who are now in their last scene of probation, to the dignity from which they were degraded, out of the language of angels, into the well-known Sanscrit language, and called his translation the *Six Scriptures of Divine Words of the Mighty Spirit.* He appointed the Brahmins, deriving their name from him, to preach the word of God; and the doctrines of the Shaster were accordingly preached in their original purity a thousand years. About this time there was published a paraphrase on the Chartah Bhade, or Six Scriptures; and about five hundred years afterwards a second exposition appeared, called the *Eighteen Books of Divine Words*, written in a character compounded of the common Hindustan and the Sanscrit. This innovation produced a schism among the Gentoos; on which occasion, it is said, those of Coromandel and Malabar formed a scripture of their own, which they pretended to be founded on the Chartah Bhade of Brahma, and called it the Vedam of Birmah, or *Divine Words of the Mighty Spirit.* The original Chartah Bhade was thrown aside, and at length wholly unknown, except to a few families, who can still read and expound it in the Sanscrit character. With the establishment of the Aughtorrah Bhade and Vedam, which, according to the Gentoo account, is 3366 years ago, their polytheism commenced; and the principles of religion became so obscure, and their ceremonies so numerous, that every head of a family was obliged to keep a Brahmin as a guide both in faith and practice. Mr Holwell is of opinion that the Chartah Bhade, or original scriptures, are not copied from any other system of theology promulgated to or obtruded upon mankind. The Gentoos do not attribute them to Zoroaster; and Mr Holwell supposes that both Zoroaster and Pythagoras visited Hindustan, not to instruct, but to be instructed.

From the account of Mr Dow, we learn that the books which contain the religion and philosophy of the Hindus are distinguished by the name of *Vedas;* that they are four in number, and, like the sacred writings of other nations, are said to have been penned by the Divinity. Veda, he says, in the Sanscrit language, literally signifies *science;* and these books treat not only of religion and moral duties, but of every branch of philosophical knowledge. The Brahmins maintain that the Vedas are the divine laws which Brahma, at the creation of the world, delivered for the instruction of mankind; but they affirm that their meaning was perverted in the first age by the ignorance and wickedness of some princes, whom they represent as evil spirits, who then haunted the earth.

The first credible account we have of the Vedas is, that about the commencement of the Cal Jug, of which era the year 1768 was the 4886th year, they were written, or rather collected, by a great philosopher and reputed prophet, called Beäss Muni, or Beäss the Inspired.

The Hindus, says Mr Dow, are divided into two great religious sects: the followers of the doctrine of Bedang, which is the original Shaster or commentary upon the Vedas; and those who adhere to the principles of the Neadirsen. The original Shaster is called *Vedang*, and is a commentary upon the Vedas. This book, he says, is erroneously called in Europe the *Vedam.* It is ascribed to Beäss Muni, and is said to have been revised some years after by one Serrider Swami, since which time it has been reckoned sacred, and not subject to any farther alterations.

Almost all the Hindus of the Deccan, and those of the Malabar and Coromandel coasts, are of this sect. The followers of the Vedang Shaster do not allow that any physical evil exists. They maintain that God created all things perfectly good; but that man, being a free agent, may be guilty of moral evil, which may be injurious to himself, but can be of no detriment to the general system of nature. God, they say, being perfectly benevolent, never punished the wicked otherwise than by the pain and affliction which are the natural consequences of evil actions; and hell, therefore, is no other than a consciousness of evil.

The Neadirsen Shaster is said to have been written by a philosopher called Goutam, nearly four thousand years ago. The Brahmins, from Mr Dow's account of their sacred books, appear to believe invariably in the unity, eternity, omniscience, and omnipotence of God; and the polytheism of which they have been accused is no more than a symbolical worship of the divine attributes, which they divide into three classes. Under the name of Brahma, they worship the wisdom and creative power of God; under the appellation of Vishen, his providential and preserving quality; and under that of Shevah, that attribute which tends to destroy.

SHAT-UL-ARAB, a large river, or rather canal, formed by the confluence of the Euphrates and the Tigris, before they enter the Persian Gulf. It forms a broad and splendid stream; and as far as Bassora, seventy miles from its mouth, it is navigable for vessels of 500 tons burden. It is generally supposed to fall into the Persian Gulf by various mouths; but this Colonel Kinneir, in his Geographical Memoir of the Persian Empire, shows to be a mistake, as those streams, supposed to be the mouths of the Shat-ul-Arab, are really the channels through which the great river Karoon pours its waters into the Gulf. With these six eastern channels the Shat-ul-Arab communicates by an artificial cut, and receives the waters of the Karoon.

SHAW, DR THOMAS, known to the learned world by his Travels to Barbary and the Levant, was born at Kendal, in Westmoreland, about the year 1692. He was appointed chaplain to the English consul at Algiers, in which station he continued for several years; and thence took proper opportunities of travelling into different parts. He returned in 1733, was elected fellow of the Royal Society, and published the account of his travels at Oxford, 1738, folio. In 1740 he was nominated principal of St Edmond Hall, which he raised from a ruinous state by his munificence; and was regius professor of Greek at Oxford until his death, which happened in 1751. Dr Clayton, bishop of Clogher, having attacked these Travels in his Description of the East, Dr Shaw published, by way of vindication, a supplement, which is incorporated into the second edition of his Travels, prepared by himself, and published in 1757, 4to.

SHAWABAD, a district of Hindustan, in the province of Bahar, situated principally between the 25th and 26th degrees of north latitude. It has the Ganges on the north, Rotas and Bahar on the south, the district of Bahar on the east, and Chunar and Rotas on the west. This is a populous and fertile country, particularly in the northern quarter, which is watered by the Ganges and the Soane. In answer to queries circulated by the Marquis Wellesley to the collectors of the districts in 1801, it appeared that the population amounted to two millions, in the proportion of one Mahommedan to twenty Hindus. The principal towns are Buxar, Boujepoor, and Arrah; and the chief rivers are the Ganges, Soane, and Caramnassa.

SHAWLS, FIGURED. This article has, within less than forty years, become a very considerable branch of our manufactures. For a long period the district of Cashmere, a province of Hindustan, formerly subject to the king of Candahar, produced articles of this description in such perfection as to make them highly prized both in Europe and in Asia. The date at which this manufacture took its rise is not known; but ever since the British established themselves in India, Cashmere shawls have been considered as one of the most valuable manufactures of the East.

These shawls are made both long and square, the former generally measuring fifty-four inches wide, and a hundred and twenty-six long; the latter are from sixty-three to seventy-two inches square. The finest of them are composed of a material exquisitely soft and warm, surpassing in this respect probably any other material that has ever been fabricated into clothing. It is recorded that, at the most flourishing period of this manufacture, the district of Cashmere had not less than 40,000 looms or frames employed in it. This district produced also a fine article of cloth, which has also been imitated in this country, and is in extensive use, called Cashmeres or Cassimeres. These manufactures were sufficient to draw to the district of Cashmere, merchants and commercial agents from Northern India, Turkey, Persia, and Tartary; and the increasing prosperity of this industrious and ingenious people was only checked by the oppressions of their own government, or the rapacity of the bordering states.

These shawls were not more prized for their fine, soft texture, than for the chaste beautiful-coloured flowering with which they were ornamented. Long practice, united to a natural delicacy of taste, enabled the manufacturers to dye the numerous colours of an unfading and brilliant hue, and to arrange them in such a manner as to produce a harmony and elegance such as no article made in Europe has ever fully equalled. The value put upon them by the traders who brought them to the different markets runs from L.5 to L.100, and those of the finest texture and greatest extent of figure sold for still higher prices. At a time when there was a duty of eighty per cent. upon their importation into this country (when, however, many were smuggled), a celebrated dealer in the article in London possessed a shawl for which he asked five hundred guineas.[1]

As this country became more and more engaged in a variety of manufactures, and the ingenuity of so many persons was put upon the stretch, it was but natural that attention should be turned to a manufacture at once so curious and so much prized. It was long before the manufacturers of this country ascertained the material of which the Cashmerian shawls were made, or by what process they were fabricated; and hence the first specimens that were produced in imitation of them in this country were very inferior. The merit of commencing, and bringing to a high degree of perfection, British shawls, belongs exclusively to Edinburgh, and the principal seat of the manufacture all along has been in Scotland. About thirty-four years ago the late Miss Bowie, who, with her father, had for a number of years been engaged in the gold-lace manufacture, attempted to make square shawls of the more simple patterns, in imitation of the Cashmere, by means of the sewing-needle, from a fabric made of silk, spun from the waste made in reeling the finest Italian silk. This plan was tedious and expensive, and in effect fell far short of the originals.

The manufacture of damask had been carried on in Edinburgh for a long period. The process by which the figures are produced in this elegant fabric first suggested the idea that a similar contrivance might produce a close imitation of the Indian shawls, both in the form of the figures and the distribution of the colours attained. To accomplish this, and to train children to insert the coloured yarn with their fingers, were simultaneously attempted by several manufacturers in Edinburgh; but although this article was manufactured by means of the fingers in Cashmere, it was soon found that the higher price of labour in Britain rendered it hopeless to establish the shawl-manufacture on this principle.

---

[1] The duty is now (1840) thirty per cent.

The part of a loom termed a lay was at last constructed, and fitted up with boxes to hold the number of shuttles for the colours required. This the weaver managed by a simple application of the thumb of his left hand, whereby he was enabled, without stopping his loom, to throw in the coloured yarn, and make it catch the threads of the warp as they were raised by the draw-boy, and thus form the intended figure. Patterns required from five to twelve different colours, and consequently as many shuttles. The loom being mounted on a plan similar to that employed for weaving damask, required one, two, and sometimes three boys, according to the extent of the pattern, to draw up the threads in their order, the shuttle being driven through: where not required to form the figure, the coloured yarn remained loose and useless over the whole breadth of the shawl, and required to be cut off with scissors. There was thus a great waste of material; but as one weaver, with one or two boys, could produce as much work in a single week, as a Cashmerian, with still more hands, on his plan of working, could produce in twelve months, the saving was still very great. In place of using any thing like an ordinary loom, the Cashmere manufacturer had the threads called the warp placed in an upright frame, and the piece worked with the fingers much in the same way as tapestry used to be made. A single shawl of some of the most extensive patterns occupied a whole family from one to two years.

The material of which the finest shawls were made, was procured from a goat found in the range of mountains lying to the north and north-west of the district of Cashmere. This animal is called by them the Thibet-goat, after the mountains they inhabit. The skins of these animals are covered with a coat of strong hair five or six inches in length; at the roots of this hair is found, in small quantities, the very soft woolly substance of which the shawls are made. Napoleon caused a breed of these goats to be brought to France, from the hair of which shawls were made; and it has now become an article of commerce, and is spun in considerable quantities both in Britain and in France. France spun and manufactured it for several years before this country succeeded in importing or making it; and to that country we are still indebted for a superior article of yarn, which sells in this country, the doubled or warp at 48s. per pound weight, and the single or weft at 30s. There are two circumstances which must at all times make this article costly: the wool is obtained from the skin after death, and not while the animal is alive; and the fine part requires to be picked from the hairy part by the hand, no machine having yet been found capable of performing the separation adequately. It farther appears that these goats are found, in their natural state, only in ranges of the highest mountains; and as they do not yield a fleece like sheep, it is manifest that the supply of the article must at all times be very limited. During the earlier period of the manufacture of shawls in this country, they were either composed of silk spun from waste, or from a mixture of this article with the finest Saxony wool, carded and spun together; the flowering being composed of the same material, or of worsted; and some of the colours were of cotton only. In this state of the manufacture, the makers in Edinburgh received from L.2 to L.10 sterling for each shawl; and for several years the demand was good.

The shawl-manufacture was soon established in several places, more particularly at Norwich, Glasgow, Paisley, and at Lyons in France, and a variety of trials continued to be made to lessen the expense of production. The plan of mounting, at this stage of the manufacture, in preparing the loom and figure, cost in many instances from L.40 to L.50 before weaving was commenced; each loom requiring one, and some of the large patterns two and even three boys, to draw the cords during the process of weaving. There was also the expense of clipping off all the coloured yarn except such as was taken up to form the figure. To lessen these expenses various means had been tried, but without success.

Shawls, Figured.

During the short peace of Amiens in 1802, a straw-hat maker in Lyons, of the name of Jacquard, happened to see, in an English newspaper, an advertisement offering a premium to any one who should contrive a machine for making nets. This led him to turn his attention to the study of mechanics, and after many fruitless trials he succeeded in contriving a machine which fully answered the purpose. He was sent for, on this account, by Napoleon, and while at Paris, a superb shawl was about to be woven for the Empress Josephine; and for its production they employed a very costly and complicated loom, which had cost more than 20,000 francs. It appeared to Mr Jacquard that the same results might be produced by less complicated machinery. Intense study and perseverance enabled him to produce the machine that now bears his name. Mr Jacquard was rewarded with a decoration of honour, and a pension of a thousand crowns per annum, and sent with his machine to Lyons, the seat of the shawl and figured silk manufactures. This contrivance not only superseded the use of the draw-boy, but also rendered a great deal of tackling unnecessary; thus greatly simplifying and cheapening the production, not only of shawls, but also that of figured articles of every description.

It is a striking instance of the ignorance and shortsightedness of the operatives of Lyons, that when Jacquard introduced his invention, the people broke out into open rebellion. He was denounced as an enemy of the people, and as the man who had been scheming the destruction of their trade, and the starvation of themselves and their families. Three several plots were laid to assassinate him, and twice he was in great danger of losing his life. So strong was the tide of prejudice and indignation, that the machine was ordered to be openly destroyed by the public authorities, and was accordingly broken in pieces in the great square of the city.

The successful competition of foreigners, and the consequent decline of trade at a subsequent period, induced some of the more intelligent manufacturers to think of the man whose discovery was likely to bring some relief to the then depressed manufacturers of Lyons. They made an experiment, and succeeded. Silks of the greatest beauty were introduced at a lower cost, and now (1840) there is not a mechanic, either in France or in Britain, who does not acknowledge the great importance of Mr Jacquard's invention. This may be fully conceived, from the fact, that not only has it been very generally adopted by shawl-manufacturers, but by makers of all kinds of damask, whether of silk or of linen, in Britain. This improvement, together with a machine which the French had also contrived about the same time, for cutting off the spare yarn used in making the figures (which completely superseded hand-labour), were both adopted in France some time before they were introduced into Britain, which, with the advantage they derived from having good yarn from the wool of the Thibet-goat, procured for the French manufactures a decided advantage over the British for several years; and notwithstanding a nominal protecting duty of thirty per cent. (but in reality not affording more than twelve per cent. as facilities for smuggling were such, that any one could have had an insurance for goods being safely delivered in London, on paying to the French merchant twelve per cent. extra), goods were brought over in great quantities, which, together with a general desire for foreign productions, had the effect of ruining several British shawl-makers, as well as some extensive dealers in the article. The improvements invented by the French, however, quickly found their way to this country, and being applied with energy, soon produced a re-action in favour of Scotch manufacturers, and caused the French to suffer in their turn, from having made too large quantities in the hopes of retaining the London trade. British figured shawls are now manufactured equal, in point of elegance, with any produced in France, and superior to those of every other country in lowness of price. They are manufactured from the wool of the Thibet-goat, which is as soft as, and more perfect in figure than, the best Cashmere, and probably less than a tenth part of the cost. The material, however, used for the flowering, being finer, and the colours being more durable in the manufactures of Cashmere, they still retain a superiority over those of Europe.

Edinburgh, from the commencement of this manufacture, has taken the lead in most of the improvements connected with it, always producing the best goods of the kind; but from the circumstance of labour of various kinds being lower in Paisley and Glasgow, the manufacture has mostly been transferred to these places. At one time there were about a thousand hands employed in Edinburgh in this manufacture; now it scarcely gives work to one hundred.

Shawls in imitation of Cashmere are made of a very great variety of qualities. While some of those made of the finest materials and richest patterns still sell for L.8 or L.10 each, there are a great many made of a mixture of silk and cotton, silk and wool, cotton and wool, and some are made wholly of cotton, so that figured shawls can be purchased at five shillings each. It is computed that, at the present time, this description of shawls gives employment to at least 20,000 hands. A great many are exported to America, as well as to other parts of the world. See WEAVING. (B. Y.)

SHAWPOOR, a town of Hindustan, province of Gundwaneh, situated on the Rhair, a considerable river, which runs by the south side of the town, over a bed of rock, which impedes its navigation. It is a straggling town, with a small fort built of rubble-stone and mud. Long. 83. 23. E. Lat. 23. 34. N.

SHEATHING, in the nautical language, is the casing of that part of a ship which is to be under water, with firboard an inch thick; first laying hair and tar mixed together under the boards, and then nailing them on, in order to prevent worms from eating the ship's bottom. Ships of war are now generally sheathed with copper; but copper sheathing is liable to be corroded by the action of salt water, and something is still wanting to effect this purpose. It is very probable that tar might answer very well.

SHEATS, in a ship, are ropes bent to the clews of the sails, serving in the lower sails to haul aft the clews of the sail; but in topsails they serve to haul home the clew of the sail close to the yard-arm.

SHEAVE, in *Mechanics*, a solid cylindrical wheel, fixed in a channel, and moveable about an axis, being used to raise or increase the mechanical powers applied to remove any body.

SHEBBEARE, JOHN, a political writer, was born at Bideford, in Devonshire, in the year 1709. He received the rudiments of his education at the free grammar-school of Exeter. It has often been observed that the future life of a man may be gathered from his puerile character; and accordingly Shebbeare, while a boy at school, gave the strongest indications of his future eminence in misanthropy and learning, by the extraordinary tenaciousness of his memory and the readiness of his wit, as well as the malignity of his disposition. He was universally regarded as a young man of surprising genius, while at the same time he was despised for his malicious temper.

About the age of sixteen, Shebbeare was bound apprentice to an eminent surgeon in his native town, under whom he acquired a considerable share of medical knowledge. His talent for lampoon appeared at this early period, and he could not forbear from exercising it on his master; but the chief marks for the arrows of his wit were the gentlemen of the corporation, some of whom laughed at such trifles, while such as were irritable often commenced prosecutions against him, but without success. He was frequently summoned to appear at the sessions, for daring to speak and write disrespectfully of the magistrates; but the laugh was always on the side of Shebbeare.

When his time was out, he set up for himself, then discovering a taste for chemistry; soon after which he married an amiable young woman with no fortune, but of respectable connections. Failing in business at Bideford, he went to Bristol in 1736, entered into partnership with a chemist, and never afterwards visited his native town.

He was at Paris in 1752, where he obtained, it is said, the degree of doctor in medicine; a fact, however, which many are disposed to question.

His most celebrated performances were a series of letters to the People of England, written in a vigorous and energetic style, well calculated to make an impression on common readers. They galled the ministry, who at first were too eager to punish the author. On the 12th of January 1758, Lord Holdernesse signed a general warrant for apprehending the author, printer, and publishers of a wicked, audacious, and treasonable libel, entitled "A Sixth Letter to the People of England, on the progress of National Ruin; in which is shown that the present grandeur of France and calamities of this nation are owing to the influence of Hanover on the councils of England;" and having found them, to seize and apprehend them, together with their books and papers.

Government having received information that a seventh letter was in the press, all the copies were seized and suppressed by virtue of another warrant, dated the 23d of January. In Easter term an information was filed against him by the attorney-general, and on the 17th of June the information was tried, when Shebbeare was found guilty; and on the 28th of November he received sentence, by which he was fined L.5, ordered to stand in the pillory on the 5th of December at Charing Cross, to be confined three years, and to give security for his good behaviour for seven years, himself in L.500, and two others in L.250 each. During his confinement, he declared he never received as presents more than twenty guineas from all the world.

He was detained in prison during the whole time of the sentence, and with some degree of rigour. At the termination of his sentence, a new reign commenced; and shortly afterwards, during Mr Grenville's administration, a pension of L.200 a year was granted him by the crown, through the influence of Sir John Philips, and he ever after became devoted to the service of government. He was of course abused in almost every periodical work, which he seems in general to have had the good sense to neglect. Dr Smollett introduced him, in no very respectful light, under the name of Ferret, in Sir Launcelot Greaves; and Mr Hogarth made him one of the group in the third election print.

His publications of a satirical, political, and medical nature amount to thirty-four, besides a novel, called Filial Piety, in which hypocrisy and blustering courage are very properly chastised. He died on the 1st of August 1788.

SHEERGOTTA, a town of Hindustan, in the province of Bahar, eighty miles south by west from Patna. Long. 84. 55. E. Lat. 24. 32. N.

SHEERNESS, a town of the county of Kent, situated on the island of Sheppey. It stands at the point where the river Medway forms its junction with the Thames, on the right bank of the former river. It has been long a place of vast importance in a military point of view. The works having been suffered to fall into decay in the war with Holland in the reign of Charles II., the Dutch fleet attacked and destroyed the fortifications, and thus opened the way for an attack on the marine arsenal of Chatham. After the Dutch retired, the works were repaired, and have been from time to time vastly strengthened. It is now a complete marine fortress, and a powerful protection to the important anchorage at the Nore, where, in time of war, especially if the port of Antwerp should be in possession of an enemy, it is necessary always to have a strong naval force ready to act. These fortifications were found of great service during the mutiny of the fleet at the Nore in the year 1796. Many of the crews were soon tired of their state of rebellion, rose upon their committees, and slipping their cables, ran under the guns of the forts, and were protected from their associates.

It is now a regular marine arsenal, chiefly used for repairing ships, and well furnished with every necessary kind of stores, and of late years well supplied with what was previously scarce, good spring-water. It is a part of the parish of Minster, the population of which amounted in 1801 to 5561, in 1811 to 7003, in 1821 to 8414, and in 1831 to 7983. The town itself has diminished from 1422 to sixty-one inhabitants, as dwellings have been removed to make space for ports. It has a market on Saturday, and there is a chapel of ease to Minster church.

SHEFFIELD, an ancient, large, and flourishing market-town in the west riding of the county of York, 160 miles north-north-west from London. It derives its name from the river Sheaf, which here flows into the Don. These rivers descend from the boldly swelling hills west of the town, and form, with their mountain-tributaries, interesting features in that beautiful scenery for which the neighbourhood has always been noted. The town itself, which used formerly to be described as built upon a gentle hill, rising within an ample valley, has long since stretched over the ascending slopes on every side of its original site, particularly to the west, which is a large suburb of beautiful villas. The inequalities of the ground have not been compensated, either by the regularity of the streets, or by any thing like uniformity in the buildings. The town has been said to be black; and certainly the smoke emitted from upwards of one hundred steam-engine chimneys, and ten times that number of forges, workshops, &c., to say nothing of what issues from so many dwellings, in a place where coal is cheap, does occasionally form a considerable cloud; but the houses are not more dingy, and the streets generally much cleaner, than in other manufacturing towns of the same size. Few persons have approached the town in any direction, without being struck with the beauty of the surrounding neighbourhood, resembling, in many respects, the varied character of a nobleman's park; and it would be difficult to find a single street from which a glimpse of the landscape cannot be obtained. Many of the neighbouring villas are built of a light-coloured stone, while those in the town are mostly of a dark-red brick. A great proportion of the latter, particularly in the newer streets, are small, being the residences of the artisans and working classes generally, almost every family living in a separate dwelling. This independent occupancy, added to the fact that in few cases are the labours of the workmen carried on at home, bespeaks a degree of comfort and cleanliness scarcely to be looked for in buildings where a single room serves at once as the workshop of the industrious man and the residence of his family.

Sheffield is the modern capital of a somewhat undefined district, which for ages has been called Hallamshire, the present Hallam, a hamlet west of the town, having been considered the site of the ancient capital, where stood the *aula*, or chief residence of the Saxon lord.

Since the sixteenth century, the records of the place show a singularly rapid increase of the population. In 1615 the town contained 2207 souls, in 1755 this number was multiplied sixfold, in 1796 the census was 29,013, in 1821 the population of the entire parish of Sheffield was 65,275, and in 1831 the inhabitants were 91,692; at present they are estimated at 110,000. Of these, about 96,000 may be said to reside in the town and suburbs, the remainder in the out townships. A proportionate increase has taken place in the number of houses. These in 1831 were stated to be 19,700; they are now 25,000.

Sheffield has no municipal head, no stipendiary magistrate, or other paramount local governor. Some of the west-riding magistrates, generally those nearest, for none of them reside within the township, sit in the town-hall twice a week for the current disposal of offenders and other business. In the same building is held the manor court for the recovery of small debts; and here too are the offices of a night and day police. An attempt was made in 1838 to obtain a corporation, in conformity with the recent act of parliament; but a great majority of the inhabitants opposing the design, it was abandoned.

The vicinity of Sheffield abounds with the natural elements of prosperity; and of these the inhabitants were prompt to avail themselves, long before the means of a perfect intercommunication throughout the country had generalized these advantages. On every side of the town coal has been got, and actually within the town itself, the seams, although wrought for centuries, appearing in some places almost inexhaustible. With the coal is found ironstone, which is smelted in the neighbourhood; while clay, slate, and sandstone are abundant, and of excellent quality. A navigable canal, opened in 1819, completed a water-communication between Sheffield and the German Ocean; and in 1838, a railway to Rotherham (six miles) was finished. The line of a railway between Sheffield and Winchester is in progress, including a tunnel of three miles under the English Apennines. The number and rapid descent of the streams west of the town afford innumerable waterfalls, on which grinding establishments have been built, and in which, previous to the introduction of steam power, all the edge-tools and cutlery made in the district were ground and polished.

Sheffield has long been celebrated, not only throughout Great Britain, but all over the world, for its cutlery manufactures. The origin of this celebrity dates as far back as the reign of Edward III., when "Sheffield whittles," as certain common kinds of knives were then and afterwards called, appear to have been in repute. As early as the middle of the sixteenth century, the staple trade was fostered by the feudal lords of Hallamshire, there being still extant the various "acts and ordinances agreed upon by the whole fellowship of cutlers, and by the assent of George earl of Shrewsbury." About a century afterwards, when, in consequence of the growing reputation of the various articles manufactured at Sheffield, and the insufficiency of the manor court to restrain the making and vending of spurious wares, the credit of the trade was likely to be endangered, an act of parliament was obtained, by which, under certain regulations, the cutlers of Sheffield were constituted a body corporate. This important act, which bears date April 1624, was designed "for the good order and government of the makers of knives, sickles, shears, scissors, and other cutlery wares in Hallamshire, in the county of York, and parts adjoining;" the latter words having reference to a part of Derbyshire immediately south of Sheffield, where vast quantities of scythes and sickles have been made ever since the reign of Elizabeth.

The Cutlers' Company consisted of a master elected annually, two warders, six searchers, twenty-four assistants, and the commonalty. Their duties were generally to register apprentices, grant corporate marks to be struck on the wares of the members, and by other means to maintain the integrity of the staple trades. This corporation continued in force, with a slight modification, until the year 1814, when, by an act (54th Geo. III.), the local manufac-

Sheffield.

tures of Sheffield were placed on an entirely new footing; the liberty of engaging in any of the heretofore incorporated trades, either as masters or journeymen, being extended indifferently to all persons, whether freemen or strangers. The act which thus abolished the old corporation influence and jurisdiction still perpetuated its formal continuance, with power to grant marks, &c., the "master-cutler" being also the returning officer in the election of the two members of parliament for the borough of Sheffield, under the reform act. The corporation have a very handsome hall in Church Street.

Although the throwing open the old corporate trades to unrestrained competition had a considerable effect in multiplying manufacturers, yet the peculiar nature of the handicrafts generally limited in some degree the changes which, under other circumstances, might have resulted from the sudden rush of capital into a new channel. In the first place, a workmanlike expertness in any branch of cutlery cannot be acquired without a considerable period of probation. In the second place, the application of machinery could only be applied, except in the department of grinding, to a very limited extent; and, with this exception, manual labour can hardly be said to be superseded, but rather assisted, by water or steam power. There are other circumstances which have operated in the same direction, especially the division of labour in the production of a single article, which has given the artisans in one branch a control over the others. This has led the workmen generally to act in concert in all questions touching their respective departments of labour, as wages, apprentices, engagements with masters, &c. To maintain what they have considered their rights, or at least their interests, recourse has been had to various compacts formed under the designation of "Trades' Unions," frequently exhibiting all the melancholy results of illegal combinations. Nor has the mischief of these confederations been confined to portentous "strikes," contests between the masters and the journeymen; but nonjuring or suspected individuals among the latter have sometimes become victims to the vigilance and the vengeance of their banded fellows. What has been the entire effect of this system upon the trade of the town generally, and upon the present condition of the parties, it is not very easy to say. It may have kept up wages, but it has more certainly broken down that good understanding which formerly existed between masters and workmen, and driven numerous customers to foreign markets. The number of persons employed in the cutlery workshops is about 10,000.

About 700 tons of Swedish iron are annually landed at the canal wharf, which are converted in the town into the steel which is used in the manufacture of knives, scissors, razors, files, saws, axes, and various other cutting instruments. Of this really "precious metal," however, the greater part is exported to the United States in the form of tilted *cast steel;* that is, steel which, after carbonization in the original bars, is broken up and melted in a crucible, afterwards cast into a mould, and then reduced at the forges into rods of such sizes as the trade requires. Besides, three or four thousand tons of British iron are annually brought into the town, and some portion of it converted into steel for inferior purposes. There are several large establishments for the manufacture of the finer kinds of stoves, grates, and fenders. These articles are often executed in the most superb style, modellers and other artists being constantly employed in devising new patterns.

About a century ago, the art of plating upon copper with silver was discovered in Sheffield; and thus originated a trade of immense importance to the town. For many years past the quantity of wares executed in this beautiful and comparatively cheap material has been very great, including particularly urns, salvers, dishes, epergnes, candelabras, and indeed almost every article which had formerly been made of silver. The silver-plating establishments are among the most respectable in the town; their interests have also been the least fluctuating. These circumstances are due mainly to the fact, that in works of this kind a large capital must be sunk in stamps, dies, and other tools; added to which is the expense of creating new designs, and involving the consideration of taste as well as cost. Sheffield plate, for richness of design, the strength of its more precious material, and for excellence of workmanship, is everywhere in high estimation.

Manufactures in Britannia metal, which are likewise indigenous to the town, are carried on to a great extent, and to a singular degree of perfection. Nearly every one of the articles made in silver-plate are elegantly imitated in this cheap material; with the addition of vast quantities of spoons, which are first cast in metal moulds, and afterwards polished by brushing.

Latterly both the foregoing lucrative branches of trade have encountered some competition from the use of what has been termed German silver, a kind of brass, which combines the colour, lustre, and durability of silver, at a cost not greatly above that of manufactured copper.

Here are two or three large establishments for the manufacture of optical instruments, including especially curious works for the grinding of spectacle-glasses, the greater part of the trade throughout the country being supplied from Sheffield. Several of the manufacturers have show-rooms on their premises for the display of their brilliant wares, which are celebrated for the variety and beauty of the cutlery-goods which they contain; and visiters may here witness the various operations carried on in the workshops.

The town of Sheffield, in every branch of its productive industry, not only carries on a considerable home trade, but its leading wares find a market in every quarter of the globe. It is, however, to the United States of America that the largest and most constant consignments are made; and hence Sheffield participates very largely in every fluctuation which affects Transatlantic mercantile interests.

The inhabitants of Sheffield are largely provided with places for the promotion of religion, education, philanthropy, and intelligence. There are in the parish twelve churches, seven in the town and five in the rural townships, containing in all 15,160 sittings. Holy Trinity, or the parish church, is a noble Gothic structure, enclosing a parallelogram 240 feet in length by 130 feet in width. From near the centre rises a tower, containing ten very well-tuned bells, and surmounted by a lofty spire of handsome proportions. That part of the church now used for divine service was, in 1800, rebuilt from the foundation, and the interior fitted up in a solid, handsome, and commodious manner, so that the chancel alone presents any traces of antiquity.

The living is a vicarage, two parties presenting in turn, as representatives of the original grantees of the advowson in 1544. Independently of the vicarial patronage, three assistant ministers are appointed and maintained by the church burgesses.

In addition to the churches and chapels of the establishment, the Methodists, Independents, Baptists, Quakers, and Roman Catholics, have respectively large, handsome, and commodious places of worship, in the whole not fewer than twenty. Of these, six belong to the Wesleyans, and include some of the largest and most ornamental chapels in the connection.

Here is an old endowed grammar-school; a collegiate school, recently built by shareholders, at an expense of L.3000; and two charity schools, one for sixty boys, and the other for sixty girls, all conducted in conformity with the principles of the Church of England. The Wesleyan Methodists have just erected, outside the town, and at a cost of about L.15,000, a splendid proprietary school, capable of boarding and educating three hundred boys. Besides these establishments, all the religious denominations have week-day and Sunday schools in different parts of the town. A literary and philosophical society was instituted in 1822; they have a museum in the music-hall, containing handsome cabinets of fossils, minerals, objects of natural history, apparatus, &c. and a capital full-length portrait of the poet Montgomery, who has long been regarded as one of the chief ornaments of the town.

There is a large theatre, erected in 1762; and under the same roof a commodious assembly-room; and adjacent, the music-hall, in which concerts and public lectures are usually delivered. A short distance outside the town, on the west, are the botanical gardens, comprising a well-enclosed plot of eighteen acres of ground, laid out in a style of elegance, and commanding an extensive prospect. The glazed conservatories present a frontage of 300 feet. On the opposite slope is a beautiful cemetery.

The general infirmary, which was opened in 1797 for "the sick and lame poor of any nation," is a large and handsome edifice, on the north-west side of the town. A subscription of L.5000 has just been raised for the purpose of adding a fever-hospital to this noble institution. Sheffield has also a medical and anatomical school, a public dispensary, and a capital bath establishment. On a fine eminence, just outside the town, stands the Shrewsbury Hospital, a charity founded in 1673, and consisting of neat houses for eighteen men and eighteen women, the former receiving ten and the latter eight shillings a week, besides coals, coats, &c. Holliss's Hospital, in the town, contains sixteen houses for poor cotters' widows, who have each seven shillings a week. There are various other smaller charities.

From the earliest period of authentic history, the Lovetots, Furnivals, Talbots, and Howards, names of stirring interest in English annals, were successively chiefs of Hallamshire, the present Duke of Norfolk being lord of the manor of Sheffield. With the transactions of these illustrious families, the older records of their ample domain and its industrious inhabitants are so intimately mixed up, that it is hardly possible to give any history of the one without involving details concerning the other. One circumstance especially has given a universality of interest to this association, namely, the committal of the unfortunate Mary Queen of Scots to the custody of George the sixth earl of Shrewsbury, and the fact that she spent the greater part of fourteen years of her troubled life at Sheffield. The residence of the royal prisoner here was chiefly at the castle, a place of strength, formerly standing at the confluence of the rivers Sheaf and Don, at the northern angle of the town, but which was so utterly demolished after the civil wars, that its situation is at present only indicated by the historian, or by the ineffaceable names of adjacent localities. The Talbots had likewise a summer residence, called the "Manour," built on a fine eminence in the ancient "Lark," a mile east of the town: of this residence a shattered and far-conspicuous fragment remains. And here, too, the ill-fated Mary occasionally resided during her captivity; and the spot is often visited by curious or sympathizing individuals on that account. An enthusiastic admirer and apologist of Mary, Samuel Roberts, Esq. has recently erected, at an expense of several thousand pounds, and in a beautiful situation, in Sheffield Lark, a small castle, of the most exquisite architecture, which he calls "Queen's Tower."

The inhabitants of Sheffield are indebted for an elegant and most elaborate history of the ancient and modern state of their town and neighbourhood, to the Reverend Joseph Hunter, a native of the place, who, in 1819, published his "Hallamshire," in one volume folio.

Sheffield, *John*, Duke of Buckinghamshire, an eminent writer of the seventeenth and eighteenth century, of great personal bravery, and an able minister of state, was born about 1650. He lost his father at nine years of age; and his mother having married Lord Ossulston, the care of his education was left entirely to a governor, who did not greatly improve him in his studies. Finding that he was deficient in many parts of literature, he resolved to devote a certain number of hours every day to his studies; and thereby improved himself to the degree of learning which he afterwards attained. Though possessed of a good estate, he did not abandon himself to pleasure and indolence, but entered as a volunteer in the second Dutch war, and was in that famous naval engagement where the Duke of York commanded as admiral; upon which occasion his lordship behaved so gallantly, that he was appointed commander of the Royal Catharine. He afterwards made a campaign in the French service under M. de Turenne. As Tangier was in danger of being taken by the Moors, he offered to head the forces which were sent to defend it, and accordingly was appointed to command them. He was then Earl of Mulgrave, and one of the lords of the bed-chamber to Charles II. The Moors retired on the approach of his majesty's forces; and the result of the expedition was the blowing up of Tangier. He continued in several great posts during the short reign of James II. till that unfortunate prince was dethroned. Lord Mulgrave, though he paid his respects to King William before he was advanced to the throne, yet did not accept of any post in the government until some years afterwards. In the sixth year of William and Mary he was created Marquis of Normanby in the county of Lincoln. He was one of the most active and zealous opponents of the bill which took away Sir John Fenwick's life; and exerted the utmost vigour in carrying through the Treason Bill, and the bill for Triennial Parliaments. He enjoyed some considerable posts under King William, and possessed much of his favour and confidence. In 1702 he was sworn lord privy-seal; and in the same year was appointed one of the commissioners to treat of an union between England and Scotland. In 1703 he was created Duke of Normanby, and soon after Duke of Buckinghamshire. In 1711 he was made steward of her majesty's household, and president of the council. During Queen Anne's reign he was but once out of employment; and then he voluntarily resigned, being attached to what were called the Tory Principles. Her majesty offered to make him lord chancellor, but he declined the office. He was instrumental in the change of the ministry in 1710. A circumstance that reflects the highest honour on him, is the vigour with which he acted in favour of the unhappy Catalans, who were afterwards so inhumanly sacrificed. He was survived by only one legitimate son, who died at Rome in 1735; but he left several natural children. He died in 1721. He was admired by the poets of his age; by Dryden, Prior, and Garth. His Essay on Poetry was applauded by Addison, and his Rehearsal is still read with pleasure. His writings were splendidly printed in 1723, in two volumes 4to, and have since been reprinted in 1729, in two volumes 8vo. The first contains his poems on various subjects; the second, his prose works, consisting of historical memoirs, speeches in parliament, characters, dialogues, critical observations, essays, and letters. It may be proper to observe, that the edition of 1729 is castrated; some particulars relating to the revolution having given offence.

SHEICK, in the oriental customs, the person who has the care of the mosques in Egypt: his duty is the same as that of the imams at Constantinople. There are more or fewer of these to every mosque, according to its size or revenue. One of them is head over the rest, and answers to a parish priest with us, and has under him, in large mosques, the readers, and people who cry out to go to prayers; but in small mosques the sheick is obliged to do all this himself. In such it is their business to open the mosque, to cry to prayers, and to begin their short devotions at the head of the congregation, who stand rank and file in great order, and make all their motions together. Every Friday the sheick makes an harangue to his congregation.

SHEIKPOOR, a town of Hindustan, in the province of Bahar, fifty miles south-east from Patna. Long. 85. 54. E. Lat. 25. 8. N.

SHEKARPOOR, a town in the province of Sewistan or Seistan, situated on the west side of the Indus. It is a large town, with seven gates. The Hindu merchants who visit this country leave their wives and relatives here for security. It is governed by a Mahommedan chief, who pays tribute both to the Afghans and Ameers of Sinde. Long. 69. 49. E. Lat. 28. 47. N.

SHEKEL, the name of a weight and coin current among the ancient Jews. Dr Arbuthnot makes the weight of the shekel equal to 9 pennyweights $2\frac{4}{7}$ grains troy weight, and the value equal to 2s. $3\frac{3}{8}$d. sterling. The golden shekel was worth L.1. 16s. 6d.

SHEKOABAD, a town of Hindustan, in the province of Agra, thirty-five miles east-south-east from the city of Agra. Long. 78. 32. E. Lat. 27. 6. N.

SHELLAM, a town and district of the Upper Carnatic, in the south of India, between the 11th and 12th degrees of north latitude. The town is generally called the Great Shellam, to distinguish it from a smaller town. It is sixty miles west-north-west from Pondicherry. Long. 78. 33. E. Lat. 11. 39. N.

SHELLIUM, a town of Hindustan, in the Carnatic, sixty-five miles west from Madras. Long. 79. 27. E. Lat 13. 8. N.

SHELTON, a township and chapelry in the county of Stafford, in the hundred of North Pirehill, formerly a division of the parish of Stoke-upon-Trent. It is two miles east-north-east from Newcastle-under-Line, and is situated on the Trent and Mersey Canal, by which its trade is much facilitated. In this township are the potteries of the village of Etruria, erected by the scientific Mr Wedgewood, who has a villa in it remarkable for the beauty of its situation, and the classical arrangement of its architectural details. There are more than thirty manufactories in the town, which give occupation to above 5000 of the inhabitants. The place is well paved, and lighted with gas. It has a church, the patronage of which is in the rector of Stoke, in whose parish it was previous to the division of that large living. There are two dissenting places of worship, with Sunday schools, in which 600 children are instructed. The population amounted in 1811 to 5487, in 1821 to 7325, and in 1831 to 9267.

SHENSTONE, William, an admired English poet, the eldest son of a plain country gentleman, who farmed his own estate in Shropshire, was born in November 1714. He learned to read of an old dame, whom his poem of the School-Mistress has delivered to posterity; and he soon received such delight from books, that he was always calling for new entertainment, and expected that, when any of the family went to market, a new book should be brought him, which, when it came, was in fondness carried to bed, and laid beside him. It is said, that when his request had been neglected, his mother wrapped up a piece of wood of the same form, and pacified him for the night. As he grew older, he went for a while to the grammar-school in Hales-Owen, and was placed afterwards with Mr Crumpton, an eminent schoolmaster at Solihul, where he distinguished himself by the quickness of his progress. When he was young (June 1724), he was deprived of his father, and soon afterwards (August 1726) of his grandfather; and, with his brother, who died afterwards unmarried, he was left to the care of his grandmother, who managed the estate. From school he was sent, in 1732, to Pembroke College, Oxford, a society which has for a long time been eminent for English poetry and elegant literature. Here it appears that he found delight and advantage; for he continued his name there ten years, though he took no degree. After the first four years he put on the civilian's gown, but without showing any intention to engage in the profession. About the time when he went to Oxford, the death of his grandmother devolved the care of his affairs on the Reverend Mr Dolman, of Brome, in Staffordshire, whose attention he always mentioned with gratitude. At Oxford he applied to English poetry, and in 1737 published a small Miscellany, without his name. He then for a time wandered about to acquaint himself with life, and was sometimes at London, sometimes at Bath, or any place of public resort; but he did not forget his poetry. He published, in 1740, his Judgment of Hercules, addressed to Mr Lyttleton, whose interest he supported with great warmth at an election. This was two years afterwards followed by the School-Mistress. Mr Dolman, to whose care he was indebted for his ease and leisure, died in 1745, and the care of his fortune now fell upon himself. He tried to escape it a while, and lived at his house with his tenants, who were distantly related; but finding that imperfect possession inconvenient, he took the whole estate into his own hands, an event which rather improved its beauty than increased its produce. Now began his delight in rural pleasures, and his passion for rural elegance; but in time his expenses occasioned clamours that overpowered the bleat of the lamb and song of the linnet, and his groves were haunted by beings very different from fauns or fairies. He spent his estate in adorning it, and his death was probably hastened by his anxieties. He was a lamp that spent its oil in blazing. It is said, that if he had lived a little longer, he would have been assisted by a pension. Such bounty could not have been more properly bestowed; but that it was ever asked is not certain, and it is too certain that it never was enjoyed. He died at the Leasowes, of a putrid fever, on the 11th of February 1763, and was buried by the side of his brother, in the churchyard of Hales-Owen.

In his private opinions, Shenstone adhered to no particular sect, and hated all religious disputes. Tenderness, in every sense of the word, was his peculiar characteristic; and his friends, domestics, and poor neighbours, daily experienced the effects of his benevolence. This virtue he carried to an excess that seemed to border upon weakness; yet if any of his friends treated him ungenerously, he was not easily reconciled. On such occasions, however, he used to say, "I never will be a revengeful enemy; but I cannot, it is not in my nature, to be half a friend." He was no economist; for the generosity of his temper prevented his paying a proper regard to the use of money, and therefore he exceeded the bounds of his paternal fortune. But if we consider the perfect paradise into which he had converted his estate, the hospitality with which he lived, his charities to the indigent, and all out of an estate that did not exceed L.300 a year, one should rather wonder that he left any thing behind him, than blame his want of economy. He yet left more than sufficient to pay all his debts, and by his will appropriated his whole estate to that purpose. Though he had a high opinion of many of the fair sex, he forbore to marry. A passion he entertained in his youth was with difficulty surmounted. The lady was the subject of that admirable pastoral, in four parts, which has been so universally read and admired, and which, one would have thought, must have softened the proudest and most obdurate heart. His works have been published by Mr Dodsley, in three volumes 8vo. The first volume contains his poetical works, which are particularly distinguished by an amiable elegance and beautiful simplicity; the second volume contains his prose works; the third his letters and other pieces.

SHEPOORY, a town of Hindustan, in the province of Agra, thirty-five miles north-west from Narwar. Long. 77. 10. E. Lat. 25. 25. N.

SHEPPERTON, a village of the county of Middlesex, in the hundred of Spelthorne. It stands on the banks of the Thames, eighteen miles from London. The course of the river having been changed, a small part of the parish is now in the county of Surrey. There is a bridge here over the river, near to which are a number of piles, called Cowey Stakes, said to have been driven into the stream by the Britons, to prevent the army of Cæsar from fording the river. It is commonly asserted that the learned Erasmus passed much of his time, when in England, at the parsonage-house, with the incumbent, who was his intimate friend. There are many fine and pleasantly situated houses looking on the river in this place. The population amounted in 1821 to 782, and in 1831 to 847.

SHEPPEY, Isle of, an island, being part of the county of Kent, situated at the mouth of the Thames and Medway, and separated from the mainland by an arm of the sea, called the Swale, which is navigable for vessels of 200 tons burden, extending about eleven miles in length. Nearly four fifths of the island consist of rich marsh and pasture land, and the rest of very productive corn and clover lands. The best wheat of England is grown on this island, the land being well manured by the large flocks of sheep on the uplands, and by the cows and oxen on the rich meadows. Though fertile, it is deemed unhealthy; and there is a scarcity of good water, though that has been of late partially remedied by a well sunk 330 feet.

The island is in none of the hundreds of Kent, but is a liberty of itself. It contains 18,340 acres of land, has within it the towns of Sheerness and Queenborough, four parishes, and, in 1831, a population of 9867, of whom 4833 were males, and 5034 were females.

SHEPTON-MALLET, a town of the county of Somerset, in the hundred of Whitestone, 116 miles from London. It is situated on the Mendip Hills, in a district abundantly supplied with coal, to which it is principally indebted for its prosperity. It is a place of considerable woollen manufacture, chiefly of broad cloths and cassimeres. The streets are narrow and ill built. It has a large parish church; and in the centre of the town a curious market-cross, erected in the year 1500, consisting of five arches, supported by that number of pentagonal columns. The manor of Shepton-Mallet is a portion of the duchy of Cornwall. There is a well-supplied market on Fridays. The population amounted in 1821 to 5021, and in 1831 to 5330.

SHER, a town in the Mahratta territories, in the province of Malwah, ninety miles north-east from Oojain. Long. 78. 55. E. Lat. 23. 58. N.

SHERBET, or Sherbit, a compound drink, first brought into England from Turkey and Persia, consisting of water, lemon-juice, and sugar, in which are dissolved perfumed cakes made of excellent Damascus fruit, containing an infusion of some drops of rose-water. Another kind of it is made of violets, honey, and juice of raisins.

SHERBORNE, a town in the hundred of its name, in the county of Dorset, 117 miles from London. It was formerly a city, the see of a bishop, removed to Salisbury in the eleventh century. It is situated at the foot of a hill, with narrow and ill-built streets, and has no striking object except the old cathedral, now the parish church, one of the finest in the west of England. The only branch of industry is the silk trade, the throwing of which is carried on by machinery. Adjoining to the town is the magnificent seat of the Earl of Digby, Sherborne Castle, which was once the residence of Sir Walter Raleigh. The town is supplied with water by the river Ivel. There are markets on Tuesday, Thursday, and Saturday. The population amounted in 1821 to 3622, and in 1831 to 4075.

SHERBURN, a town of the west riding of the county of York, in the wapentake of Barkston Ash. It is situated on the great road from Doncaster to York, 185 miles from London. It was once a place of more importance than it is at present, having been the seat of an archbishop, of whose palace no vestige now remains; but there is a fine old church. The place is celebrated for its cherry-orchards, and for a peculiar kind of plums. The population of the town amounted in 1821 to 1144, and in 1831 to 1155; but the parish extends over six other townships, whose aggregate population amounted in 1821 to 2916, and in 1831 to 3068.

SHEREGUR, a town of the Sikh territories, in the province of Mooltan, seventy miles south-south-west from Lahore. Long. 73. 24. E. Lat. 30. 55. N.

SHERIBON. See Cheribon.

SHERIDAN, Thomas, D.D., the intimate friend of Dean Swift, is said by Shield, in Cibber's Lives of the Poets, to have been born about 1684, in the county of Cavan, where, according to the same authority, his parents lived in no very elevated state. They are described as being unable to afford their son the advantages of a liberal education; but he, being observed to give early indications of genius, attracted the notice of a friend of his family, who sent him to the college of Dublin, and contributed towards his support while he remained there. He afterwards entered into orders, and set up a school in Dublin, which long maintained a very high reputation, as well for the attention bestowed on the morals of the scholars, as for their proficiency in literature. So great was the estimation which this seminary enjoyed, that it is asserted to have produced in some years the sum of L.1000. It does not appear that he had any considerable preferment; but his intimacy with Swift procured for him, in 1725, a living in the south of Ireland, worth about L.150 a year, which he went to take possession of, and, by an act of inadvertence, destroyed all his future expectations of rising in the church; for, being at Cork on the 1st of August, the anniversary of King George's birth-day, he preached a sermon which had for its text, "Sufficient for the day is the evil thereof." On this being known, he was struck out of the list of chaplains to the lord lieutenant, and forbidden the Castle.

This living Dr Sheridan afterwards changed for that of Dunboyne, which, by the knavery of the farmers, and the power of the gentlemen in the neighbourhood, fell so low as L.80 per annum. He gave it up for the free school of Cavan, where he might have lived well in so cheap a country on a salary of L.80 a year, besides his scholars; but the air being, as he said, too moist and unwholesome, and being disgusted with some persons who lived there, he sold the school for about L.400; and having soon spent the money, he fell into bad health, and died on the 10th of September 1738, in his fifty-fifth year.

Lord Cork has given the following character of him. "Dr Sheridan was a schoolmaster, and in many instances perfectly well adapted for that station. He was deeply versed in the Greek and Roman languages, and in their customs and antiquities. He had that kind of good nature which absence of mind, indolence of body, and carelessness of fortune, produce; and although not over strict in his own conduct, yet he took care of the morality of his scholars, whom he sent to the university remarkably well founded in all kinds of classical learning, and not ill instructed in the social duties of life. He was slovenly, indigent, and cheerful. He knew books much better than men; and he knew the value of money least of all. In this situation, and with this disposition, Swift fastened upon him as upon a prey with which he intended to regale himself whenever his appetite should prompt him." His lordship then mentions the event of the unlucky sermon, and adds, "This ill-starred, good-natured, improvident man returned to Dublin, unhinged from all favour at court, and even banished from the Castle. But still he remained a punster, a quibbler, a fiddler, and a wit. Not a day passed without a rebus, an anagram, or a madrigal."

One of the volumes of Swift's miscellanies consists almost entirely of letters between him and the dean. He published a prose translation of Persius; to which he added the best notes of former editors, together with many judicious ones of his own. This work was printed at London, 1739, in 12mo.

Sheridan, *Mrs Frances*, wife of Thomas Sheridan, A.M. was born in Ireland about the year 1724, but descended from a good English family which had removed thither. Her maiden name was Chamberlaine, and she was granddaughter of Sir Oliver Chamberlaine. The first literary performance by which she distinguished herself, was a little pamphlet at the time of a violent party-dispute relative to the theatre, in which Mr Sheridan had newly embarked his fortune. So well-timed a work exciting the attention of Mr Sheridan, he by an accident discovered his fair patroness, to whom he was soon afterwards married. She was a person of the most amiable character in every relation of life, with the most engaging manners. After lingering some years in a very weak state of health, she died at Blois, in the south of France, in the year 1767. Her Sidney Biddulph may be ranked with the first productions of that class in ours or in any other language. She also wrote a little romance, in one volume, called Nourjahad, in which there is a great deal of imagination, productive of an admirable moral. She was likewise the authoress of two comedies, The Discovery, and The Dupe.

Sheridan, *Richard Brinsley*, a distinguished dramatist and politician, was born at Dublin in the month of September 1757, and baptized in St Mary's Church on the fourth of the following month. His grandfather and father each attained a celebrity, by the friendship with which the former was honoured by Swift, and by the competition, and even rivalry, which the latter so long maintained with Garrick. His mother, too, was a woman of considerable talents. Her affecting novel, Sidney Biddulph, could boast amongst its panegyrists Mr Fox and Lord North; and in the tale of Nourjahad she employed the graces of oriental fiction to deceive her readers into a taste for true happiness and virtue.

At the age of seven years, Richard Brinsley Sheridan was, with his eldest brother Charles Francis, placed under the tuition of Mr Samuel Whyte of Grafton Street, Dublin; and after being little more than a year under his care, they were removed to England, where Mr and Mrs Sheridan had lately gone to reside. In the year 1762, Richard was sent to Harrow, Charles being kept at home as a fitter subject for the instructions of the father. At that time, Dr Sumner was at the head of the school, and Dr Parr, who to the massy erudition of a former age joined the free and enlightened intelligence of the present, was one of the under masters. Both he and Dr Sumner endeavoured, by all possible means, to awaken in Sheridan a consciousness of those powers which he manifestly possessed; but remonstrance and encouragement were equally thrown away upon the good-humoured indifference of their pupil. One of the most valuable acquisitions he derived from Harrow, however, was that friendship with Dr Parr, which lasted throughout his life, and which identity of political opinion tended not a little to invigorate.

On his leaving Harrow, where he continued until about his eighteenth year, he was brought home by his father, who, with the elder son, Charles, had lately returned from France, and taken a house in London. Here the two brothers for some time received private tuition from Mr Lewis Kerr, an Irish gentleman, who had formerly practised as a physician; and they also attended the fencing and riding schools of Mr Angelo, at the same time receiving from their father instructions in English grammar and oratory. Of this advantage, however, the elder son appears alone to have availed himself; and Richard, determined to owe all to nature, was found as impracticable a pupil at home as at school. But, however inattentive to his studies he may have been at Harrow, it is evident, from a letter of his school-fellow, Mr Halhed, that he had already distinguished himself in poetry, and, in conjunction with his friend, had translated the seventh Idyl, and many of the lesser poems of Theocritus. In the year 1770, when Halhed was at Oxford, and Sheridan with his father at Bath, they commenced a correspondence (of which Halhed's share only remains), and, with all the hope and spirit of young adventurers, began and prosecuted several works, of which none but their translation of Aristænetus ever saw the light.

In this copartnership of genius, their first joint production was a play in three acts, called *Jupiter*, written in imitation of the burletta of Midas. Of this piece Halhed, who had furnished the burlesque scenes, entertained great hopes; nor were those of Sheridan less earnest and sanguine; yet that habit of dilatoriness, which is too often attendant upon genius, and which, throughout life, was remarkable in the character of Mr Sheridan, prevailed so far, that though he received from his friend the sketch of this piece in 1770, it was not till May next year that the probability of the arrival of the manuscript was announced to Mr Foote. Another of their projects was a periodical miscellany, the idea of which originated with Sheridan. The title intended by him for this paper was Hernan's Miscellany, to which Halhed objected, and proposed The Reformer, as a newer and better name. But this paper, for want of auxiliaries, never proceeded beyond the first number, which was written by Sheridan. It is the characteristic of fools to be always beginning; and this is not the only point in which folly and genius resemble each other. Amongst the many literary works projected by Sheridan at this period, were a collection of Occasional Poems, and a volume of Crazy Tales, to the former of which Halhed suggests, that "the old things they did at Harrow, out of Theocritus," might form a useful contribution. But neither of these came to any thing; and the translation of Aristænetus was the only fruit of their literary alliance that, as we have already stated, ever arrived at sufficient maturity for publication.

The passion, however, that now began to take possession of his heart was little favourable to his advancement in serious studies. In the neighbourhood of Miss Linley, the arts and the sciences were suffered to fall asleep, and even the translation of Aristænetus itself proceeded but slowly. After various fortune, however, it at length made its appearance in August 1771, contrary to the advice of the bookseller, and, as it might have been expected, from the unpropitious season at which it appeared, complete failure was the consequence. The disappointment of the authors was no doubt proportioned to the sanguine expectations they had indulged. But as to Mr Sheridan, he sought for consolation in the society of Miss Linley, who had now become the star of his attraction, and the centre round which revolved all his hopes. This lady, indeed, notwithstanding the drawback of her profession as a singer, appears to have spread her gentle conquests to an extent almost unparalleled in the annals of beauty. "Her personal charms, the exquisiteness of her musical talents, and the full light of publicity which her profession threw upon both," says Mr Moore, "naturally attracted round her a crowd of admirers, in whom the sympathy of common pursuit soon kindled into rivalry, till she became at length an object of vanity as well as of love. Her extreme youth, too (for she was little more than sixteen when Sheridan first met her), must have removed, even from minds the most fastidious and delicate, that repugnance they might have justly felt to her profession, if she had lived much longer under its tarnishing influence, or lost, by frequent exhibitions before the public, that fine gloss of feminine modesty, for whose absence not all the talents and accomplishments of the whole sex can atone."

Even at this early age, she had been on the point of marriage with Mr Long, an old gentleman of considerable fortune in Wiltshire; but, on her secretly representing to him, that she never could be happy as his wife, he generously took upon himself the whole blame of breaking off the alliance, and even indemnified the father by settling L.3000 upon his daughter. Mr Sheridan, who owed to this liberality not only the possession of the woman he loved, but the means of supporting her during the first years of their marriage, uniformly spoke of Mr Long with all the kindness and respect which such a disinterested character merited. Meanwhile, in love, as in all besides, the power of a mind like Sheridan's made itself felt through all obstacles; and he won the entire affections of the Syren, though the number and wealth of his rivals, amongst whom were a brother and friend, the ambitious views of the father, and the temptations to which she was hourly exposed, kept his fears and jealousies continually on the watch. But, whilst this was the case, a new and unexpected difficulty awaited him.

Captain Mathews, a married man, and intimate with Miss Linley's family, had for some time harassed her with those discreditable addresses, which it is equally painful to disclose and intolerable to endure. To the threat of self-destruction, he is said to have added the still more unmanly menace of ruining her reputation, if he could not undermine her virtue. Terrified by his perseverance, she confided her distresses to Sheridan, who lost no time in expostulating with him upon the cruelty, libertinism, and hopelessness of his pursuit. Such a remonstrance, however, was but little calculated to conciliate the forbearance of this professed man of gallantry; so that, early in 1772, Miss Linley adopted the resolution of flying to France, and taking refuge in a convent. At this time Sheridan was little more than twenty, and Miss Linley just entering her eighteenth year. Landing at Dunkirk, they proceeded to Lisle, where they procured an apartment in a convent, with the intention of remaining there until Sheridan should have the means of supporting her as his wife. On the first discovery of the elopement, Mathews busied himself making inquiries into the affair. During the four or five weeks that the young couple were absent, he never ceased to haunt the Sheridan family with all sorts of exaggerated rumours; and at length, urged on by the restlessness of revenge, he inserted a violent and inflammatory advertisement in the Bath Chronicle, in which he publicly posted Mr Sheridan as a scoundrel and a liar. The consequences of this were such as might have been expected. The party now returned from the Continent, and, without loss of time, Sheridan called out Mathews. His second on the occasion was Mr Ewart, and the particulars of the duel, which was fought with swords, are stated by himself in a letter addressed to Captain Knight, the second of Mathews. From this it appears that Mathews, being worsted, was obliged to beg his life; after which he signed an ample apology, in which he retracted the expressions he had made use of, as "the effects of passion and misrepresentation," and begged pardon for his advertisement in the Bath Chronicle.

With the odour of this transaction fresh about him, Mr Mathews retired to his estate in Wales, and there found himself universally shunned. An apology may be, according to circumstances, either the noblest effort of manliness, or the last resource of fear; and, from the reception which this gentleman everywhere experienced, it is evident that to the latter class of cases his late retraction had been referred. In this crisis, a Mr Barnett, who had but lately come to reside in his neighbourhood, took upon himself the duty of urging a second meeting with Sheridan, as the only means of removing the stigma left by the first; offering, at the same time, to be the bearer of the challenge. This offer was accepted, and the parties met at Kingsdown, where a desperate encounter ensued, in which Mr Sheridan's sword was broken, and himself severely wounded. A narrative of this affair, drawn up by Mr Barnett, and sanctioned by the concurrence of Captain Paumier (Sheridan's friend) in the truth of its material facts, was soon afterwards published; whilst the comments which Sheridan thought it necessary to make have been found in an unfinished state amongst his papers. As soon as Sheridan was sufficiently recovered of his wounds, his father sent him to pass some months at Waltham Abbey, Essex, where he continued, with but a few short intervals of absence, from August or September 1772, till the spring of the following year.

During this period, he evinced considerable industry, particularly in an abstract which he made of the History of England, and in a collection of remarks on Sir William Temple's works, especially his essay on Popular Discontents, on which his observations are tasteful and just. Still his situation was at this time singularly perplexing. He had won the heart, and even the hand, of the woman he loved, yet saw his hopes of possessing her farther off than ever. He had twice risked his life against an unworthy antagonist, yet found the vindication of his honour incomplete. He felt within himself all the proud consciousness of genius, yet, thrown upon the world without a profession, he looked in vain for a channel through which to direct its energies. Even the precarious hope which his father's favour held out had been purchased by an act of duplicity, which his conscience condemned; for he not only had promised that he would instantly abandon the pursuit, but had even taken an oath that he would never marry Miss Linley. To a mind so young and so ardent, the pressure of these various anxieties must, of course, have been great; in fact they could only have been adequately described by him who felt them; and there still exist some letters, written by him during this time, which betray a sadness and despondency, sometimes breaking out into aspirings of ambition, sometimes rising even into a tone of cheerfulness, that ill concealed the melancholy underneath. But it was impossible that Sheridan could be always under a cloud. Misunderstandings there no doubt were, arising probably from those paroxysms of jealousy into which he must have been continually thrown; but reconcilement was with no great difficulty effected; and at length Mr Linley, convinced that it was impossible to keep them much longer asunder, consented to their union, which took place on the 13th of April 1773.

A few weeks previous to his marriage, Sheridan had been entered a student of the Middle Temple. It was not to be expected, however, that talents like his would submit to toil for the distant and dearly-earned emoluments which a life of labour in this profession might secure; nor, indeed, did his circumstances admit of any such patient speculation. A part of the sum which Mr Long had settled upon Miss Linley, and occasional assistance from her father, were now the only resources left him, besides his own talents. Mrs Sheridan's celebrity as a singer was a ready source of wealth, and offers of the most advantageous kind were pressed upon them by the managers of concerts, both in town and country. But her husband at once rejected all thoughts of allowing her to re-appear in public, and, instead of profiting by the display of his wife's talents, adopted the manlier resolution of seeking independence by his own. How decided his mind was upon the subject, appears by a letter written to Mr Linley about a month after the marriage. At East Burnham, whence this letter is dated, they were now living in a small cottage, to which they had retired immediately on their marriage; and to it they often looked back with a sigh, in after times, when they were more prosperous and less happy. Towards winter they went to lodge for a short time with Storace, the intimate friend of Mr Linley, and in the following year attained that first step towards independence, a house to themselves. During the summer of 1774, they passed some time at Mr Canning's and Lord Coventry's; but so little did these visits interfere with the literary industry of Mr Sheridan, that he had not only at that time finished his play of the Rivals, but was on the point of "sending a book to press."

On the 17th of January 1775, the comedy of the Rivals was brought out at Covent Garden. This play failed on its first representation, chiefly owing to the bad acting of Mr Lee in Sir Lucius O'Trigger. Another actor was, however, substituted in his stead, and the play being lightened of this and some other incumbrances, rose at once in public favour and patronage. The best comment on this lively play is to be found in the many smiling faces that are lighted up whenever it appears. With much less wit, it exhibits more humour than the School for Scandal, and the dialogue is more natural, as coming nearer the current of ordinary conversation. The characters, however, are not such as occur very commonly in the world, and for our knowledge of them we are indebted to their confessions rather than to their actions. Lydia Languish, in proclaiming the extravagance of her own romantic notions, prepares us for events much more ludicrous and eccentric than those in which she is concerned; in the composition of Sir Lucius O'Trigger, his love of fighting is the only characteristic strongly brought out; and the wayward, captious jealousy of Falkland, though so highly coloured in his own representation, is productive of nothing answerable to such an announcement. The character of Sir Anthony Absolute is perhaps the best sustained and most natural of any, and the scenes between him and Captain Absolute are genuinely dramatic. Mrs Malaprop's mistakes have often been objected as improbable from a woman in her rank of life; but though some of them are extravagant and farcical, they are almost all amusing; and the luckiness of her simile, "as headstrong as an *allegory* on the banks of the Nile," has been acknowledged by all whose taste is not too refined to be moved by the genuine comic.

Mr Sheridan now employed the summer recess in writing the Duenna, whilst his father-in-law, Mr Linley, assisted in selecting and composing the music for it. In hands so willing, the work made speedy progress, and, on the 21st November, the Duenna was performed at Covent Garden. The run of this opera has, we believe, no parallel in the annals of the drama. The Beggar's Opera had a career of sixty-three nights; but the Duenna, more fortunate, was acted no less than seventy-five times during the season, the only intermissions being a few days at Christmas, and the Fridays in every week. In order to counteract this great success of the rival house, Garrick found it necessary to bring forward all the weight of his best characters; and he had even recourse to the expedient of playing off the mother against the son, by reviving Mrs Frances Sheridan's comedy of the Discovery, and acting the leading character in it himself. The Duenna, in fact, is one of the very few operas in our language which combine the merits of legitimate comedy with the attractions of poetry and song. The "sovereign of the soul," as Gray calls music, always loses by being made exclusive sovereign; and the division of her empire with poetry and wit, as in the instance of the Duenna, doubles her real power. The intrigue of this piece is constructed and managed with considerable adroitness, having just material enough to form three acts, without being encumbered by too much intricacy, or weakened by too much extension. And as to the wit of the dialogue, except in one or two instances, it is of that accessible kind which lies near the surface, and which, as it is produced without effort, may be enjoyed without wonder.

Towards the close of the year 1775, Garrick intending to part with his moiety of the patent of Drury Lane theatre, and retire from the stage, Mr Sheridan made him an offer as purchaser, and eventually became patentee and manager. The progress of the negociation cannot be better related than in some of Sheridan's own letters, addressed to Mr Linley, which Mr Moore has printed. It appears, indeed, that the contract was perfected in June 1776; and in a paper drawn up by Mr Sheridan many years afterwards, the shares of the respective purchasers are thus stated, viz. Mr Sheridan, two fourteenths of the whole, L.10,000; Mr Linley, the same, L.10,000; and Dr Ford, three fourteenths, L.15,000. Whence Mr Sheridan's supply came, or to whom he was indebted for this seasonable aid, has never been known. Not even to Mr Linley, whilst entering into all other details, does he hint at the fountain-head from which it was to come; and, indeed, there was something mysterious about all his acquisitions, whether in love or in learning, in wit or in wealth. Finally, in reference to this subject, the first contribution which the new manager furnished to the stock of the theatre was an alteration of Vanburgh's comedy, the Relapse, which was brought out on the 24th of February 1777, under the title of a Trip to Scarborough.

Mr Sheridan was now approaching the summit of his dramatic fame. He had already produced the best opera in the language, and there now remained for him the glory of writing also the best comedy. As this is a species of composition which, more perhaps than any other, seems to require a knowledge of human nature and the world, it is not a little extraordinary that nearly all our first-rate comedies should have been the productions of very young men. Those of Congreve were all written before he was five-and-twenty. Farquhar produced the Constant Couple in his two-and-twentieth year, and died at thirty. Vanburgh was a young ensign when he sketched out the Relapse and the Provoked Wife; and Sheridan crowned his reputation with the School for Scandal at six-and-twenty. And it is still more remarkable to find, as in the instance before us, that works, which we might suppose to have been the offspring of a careless but vigorous fancy, should, on the contrary, have been the slow result of many doubtful experiments, gradually unfolding beauties unseen even by him who produced them, and at length arriving step by step at perfection. That the School for Scandal was produced by this tardy process, is evident from the sketches of its plan and dialogue which Mr Moore has produced, and which serve to throw a remarkable light on the first slow workings of genius, out of which its finest transmutations arise. The reader who may feel curious on this subject is referred to Mr Moore's clear and masterly exposition. Suffice it to mention, that there are two distinct sketches, in the second of which particularly, is shown the condensing process which his wit must have gone through before it attained its present proof and flavour. There appear also to have been originally two plots, which the author incorporated into one; yet, even in the details of the new plan, considerable alterations were subsequently made, entire scenes suppressed or transposed, and the dialogue of some completely rewritten.

This play was produced on the 8th of May 1777, and its success was decided and triumphant. Indeed, long after its first uninterrupted run, it continued to be played regularly two or three times a week; and on comparing the receipts of the first twelve nights with those of a later period, it will appear how little the attraction of the piece had abated by repetition. The beauties of this comedy are so universally known, that it cannot be necessary to dwell upon them. With but little interest in the plot, no very profound or ingenious development of character, and a group of personages, not one of whom has any legitimate claims upon either our affection or esteem, it yet, by the admirable skill with which its materials are managed, the happy contrivance of the situations, that perpetual play of wit which never tires, and a finish almost faultless, it unites the suffrages at once of the refined and the simple, and is not less successful in satisfying the tastes of the one, than in ministering to the enjoyment of the other. And this is the true triumph of genius in all the arts. In painting, sculpture, music, or literature, those works which have pleased the greatest number for the longest space of time, may be pronounced the best; for, however mediocrity may enshrine itself in the admiration of the few, the palm of excellence can only be awarded by the many. The defects of the School for Scandal, if they can be allowed to amount to defects, are in a great measure traceable to the amalgamation of two distinct plots, out of which the piece was formed. From this cause has devolved that excessive opulence with which the dialogue is almost overloaded, and which Sheridan himself used to mention as a fault which he was conscious of in his work. From beginning to end, it is a continued sparkling of point and polish; and the whole of the characters might be comprehended under one common designation of wits, even Trip, the servant, being as shining and brilliant as the rest. "In short," says Mr Moore, "the entire comedy is a sort of El Dorado of wit, where the precious metal is thrown about by all classes, as carelessly as if they had not the least idea of its value."

Soon after the appearance of this comedy, Sheridan made a further purchase of theatrical property, amounting to L.17,000; and amongst the visible signs of his increased influence in the affairs of the house, was the appointment, this year, of his father to be manager. At the beginning of the year 1779, Garrick died, and Sheridan, who had followed his body to the grave, wrote a monody to his memory, which was recited after the play in the month of March following. In the course of the same year he produced the entertainment of the Critic, which was his last legitimate offering at the shrine of the dramatic muse. In this incomparable farce, we have a striking instance of the privilege which genius assumes of taking up subjects that had passed through other hands, and giving them new value and currency. The plan of the Rehearsal was first adopted for the purpose of ridiculing Dryden; but although there is much laughable humour in some of the dialogue, the salt was not of a very conservative nature, and the piece continued to be served up to the public long after it had lost its relish. Fielding tried the same plan in a variety of productions, but without much success, except, perhaps, in the comedy of Pasquin. It was reserved for Sheridan to give vitality to this form of dramatic humour, and to invest even his satirical portraits with a generic, which, without weakening the particular resemblance, makes them representatives of the whole class to which the original belonged. Bayes, on the other hand, is a caricature made up of little more than personal peculiarities, but may amuse as long as reference may be had to the prototype, but fall lifeless the moment the individual that supplied them is no more.

Having terminated his dramatic career, in which he had been eminently successful, Sheridan now prepared to act a part in a widely different scene. His thoughts had been gradually drawn to the seducing subject of politics, on which he had tried his hand at some very fair remarks on absenteeism; he had also rendered some service to the party with which he had connected himself, by taking an active share in a periodical publication called the Englishman; and his first appearance before the public was made in conjunction with Mr Fox, at the beginning of 1780, when the Resolutions on the State of the Representation, together with a Report on the same subject, were laid before the public. The dissolution of parliament, which took place in the autumn of 1780, at length afforded the opportunity to which his ambition had so eagerly looked forward; and Stafford was destined to have the honour of first choosing him for its representative. It is not our intention, however, to investigate his political with the same minuteness as his literary life; and this is the less necessary, seeing that the amplest narrative would probably be the heaviest, and that the masterly pen of Lord Brougham has sketched an outline which must be fully sufficient to satisfy the inquiries of the most curious and inquisitive.

"His first effort," says Lord Brougham, "was unambitious, and it was unsuccessful. Aiming at but a low flight, he failed in that humble attempt. An experienced judge, Woodfall, told him it would never do; and counselled him to seek again the more congenial atmosphere of Drury Lane. But he was resolved that it should do; he had taken his part; and as he felt the matter was in him, he vowed not to desist till he had brought it out. What he wanted in acquired learning and natural quickness, he made up by indefatigable industry. Within given limits, towards a present object, no labour could daunt him; no man could work for a season with more steady and unwearied application. By constant practice in small matters, or before private committees, by diligent attendance upon all debates, by habitual intercourse with all dealers in political wares, from the chiefs of parties and their more refined coteries, to the providers of daily discussion for the public, and the chroniclers of parliamentary speeches, he trained himself to a facility of speaking, absolutely essential to all but first-rate genius, and all but necessary even to that; and he acquired what acquaintance with the science of politics he ever possessed, or his speeches ever betrayed. By these steps he rose to the rank of a first-rate speaker, and as great a debater as a want of readiness, and need for preparation, would permit.

"He had some qualities which led him to this rank, and which only required the habit of speech to bring them out into successful exhibition; a warm imagination, though more prone to repeat with variations the combinations of others, or to combine anew their creations, than to bring forth original productions; a fierce, dauntless spirit of attack; a familiarity, acquired from his dramatic studies, with the feelings of the heart and the ways to touch its chords; a facility of epigram and point, the yet more direct gift of the same theatrical apprenticeship; an excellent manner, not unconnected with that experience; and a depth of voice which perfectly suited the tone of his declamation, be it invective, or be it descriptive, or be it impassioned. His wit, derived from the same source, or sharpened by the same previous habits, was eminently brilliant, and almost always successful. It was, like all his speaking, exceedingly prepared, but it was skilfully introduced, and happily applied; and it was well mingled also with humour, occasionally descending to farce. How little it was the inspiration of the moment, all men were aware who knew his habits; but a singular proof of this was presented by Mr Moore when he came to write his life; for we there find given to the world, with a frankness which must almost have made the author shake in his grave, the secret note-books of this famous wit; and are thus enabled to trace his jokes, in embryo, with which he had so often made the walls of St Stephen's shake, in a merriment excited by the happy appearance of sudden unpremeditated effusion.

"The adroitness with which he turned to account sudden occasions of popular excitement, and often at the expense of the Whig party, generally too indifferent to such advantages, and too insensible to the damage they thus sustained in public estimation, is well known. On the mutiny in the fleet, he was beyond all question right; on the French invasion, and on the attacks upon Napoleon, he was almost as certainly wrong; but these appeals to the people, and to the national feelings of the House, tended to make the orator well received, if they added little to the statesman's reputation; and of the latter character he was not ambitious. His most celebrated speech was certainly the one upon the Begum charge, in the proceedings against Hastings; and nothing can exceed the accounts left us of

Sheridan.

its unprecedented success. Not only the practice then first began, which has gradually increased till it greets every good speech, of cheering, on the speaker resuming his seat, but the minister besought the House to adjourn the decision of the question, as being incapacitated from forming a just judgment under the influence of such powerful eloquence; whilst all men on all sides vied with each other in extolling so wonderful a performance. Nevertheless, the opinion has now become greatly prevalent, that a portion of this success was owing to the speech having so greatly surpassed all the speaker's former efforts, to the extreme interest of the topics which the subject naturally presented, and to the artist-like elaboration and beautiful delivery of certain fine passages, rather than to the merits of the whole. Certain it is, that the repetition of great part of it, presented in the short-hand notes of the speech on the same charge, in Westminster Hall, disppoints every reader who has heard of the success which attended the earlier effort. In truth, Mr Sheridan's taste was very far from being chaste, or even moderately correct. He delighted in gaudy figures; he was attracted by glare, and cared not whether the brilliancy came from tinsel or gold, from broken glass or pure diamond; he overlaid his thoughts with epigrammatic diction; he 'played to the galleries,' and indulged them, of course, with an endless succession of claptraps. His worst passages by far were those which he evidently preferred himself, full of imagery, often far-fetched, oftener gorgeous, and loaded with point that drew the attention of the hearer away from the thoughts to the words; and his best by far were those where he declaimed, with his deep clear voice, though somewhat thick utterance, with a fierce defiance of some adversary, or an unappeasable vengeance against some oppressive act; or reasoned rapidly, in the like tone, upon some plain matter of fact, or exposed as plainly to homely ridicule some puerile sophism; and in all this his admirable manner was aided by an eye singularly piercing,[1] and a countenance which, though coarse, and even in some features gross, was yet animated and expressive, and could easily assume the figure of both rage, and menace, and scorn. The few sentences with which he thrilled the House, on the liberty of the press, in 1810, were worth, perhaps, more than all his elaborated epigrams and forced flowers on the Begum charge, or all his denunciations of Napoleon, 'whose morning orisons and evening prayers are for the conquest of England, whether he bends to the God of Battles or worships the Goddess of Reason;' certainly far better than such pictures of his power, as his having 'thrones for his watchtowers, kings for his sentinels, and for the palisades of his castle sceptres stuck with crowns.' 'Give them,' said he in 1810, and in a far higher strain of eloquence, 'a corrupt House of Lords; give them a venal House of Commons; give them a tyrannical prince; give them a truckling court,—and let me but have an unfettered press; I will defy them to encroach a hair's breadth upon the liberties of England.' Of all his speeches, there can be little doubt that the most powerful, as the most chaste, was his reply, in 1805, upon the motion which he had made for repealing the Defence Act. Mr Pitt had unwarily thrown out a sneer at his support of Mr Addington, as though it was insidious. Such a stone, cast by a person whose house, on that aspect, was one pane of glass, could not fail to call down a shower of missiles; and they who witnessed the looks and gestures of the aggressor, under the pitiless pelting of the tempest which he had provoked, represent it as certain that there were moments when he intended to fasten a personal quarrel upon the vehement and implacable declaimer.

"When the just tribute of extraordinary admiration has been bestowed upon this great orator, the whole of his praise has been exhausted. As a statesman, he is without a place in any class, or of any rank; it would be incorrect and flattering to call him a bad, or a hurtful, or a shortsighted, or a middling statesman; he was no statesman at all. As a party man, his character stood lower than it deserved, chiefly from certain personal dislikes towards him; for, with the perhaps doubtful exception of his courting popularity at his party's expense, on the two occasions already mentioned, and the much more serious charge against him of betraying his party in the Carlton House negociation of 1812, followed by his extraordinary denial of the facts when he last appeared in parliament, there can nothing be laid to his charge as inconsistent with the rules of the strictest party duty and honour; although he made as large sacrifices as any unprofessional man ever did to the cause of a long and hopeless opposition, and was often treated with unmerited coldness and disrespect by his coadjutors. But as a man his character stood confessedly low. His intemperate habits, and his pecuniary embarrassments, did not merely tend to imprudent conduct, by which himself alone might be the sufferer; they involved his family in the same fate; and they also undermined those principles of honesty which are so seldom found to survive fallen fortunes, and hardly ever can continue the ornament and the stay of ruined circumstances, when the tastes and the propensities engendered in prosperous times survive through the ungenial season of adversity."

Sherlo

Sheridan was indeed most unfortunate. Whilst death was fast gaining on him, the miseries of life were thickening around him; nor did the last corner where he now lay down to die, afford him any asylum from the clamours of his legal pursuers. Writs and executions came in rapid succession, and bailiffs at length got possession of the house. A sheriff's officer arrested the dying man in his bed, and was about to carry him off in his blankets to a spunging house, when he was prevented by an intimation of the responsibility he must incur, if, as was but too probable, his prisoner should expire on the way. In the mean time, the attention and sympathy of the public were awakened to the desolate condition of Sheridan, by an article which appeared in the Morning Post, written, it seems, by a gentleman who, though on no very cordial terms with him, forgot every other feeling in a generous pity for his fate, and in honest indignation against those who had deserted him. But it was now too late. Its effect, indeed, was soon visible in the calls made at Sheridan's door, amongst which the Duke of York and the Duke of Argyll appeared as visiters; but the spirit that these unavailing tributes might once have comforted was fast losing the consciousness of every thing earthly; and, after a succession of shivering fits, he fell into a state of exhaustion, which continued till his death. He expired on Sunday, the 7th of July 1816, in the sixty-fifth year of his age, and was buried on the Saturday following, many royal and noble persons crowding round his insensible clay, whose notice, had it been earlier, might have soothed and comforted his death-bed, and saved his heart from breaking. (A.)

SHERLOCK, William, a learned English divine in the seventeenth century, was born in 1641, and educated at Eton school, where he distinguished himself by the vigour of his genius and his application to study. From this he was removed to Cambridge, where he took his degrees. In 1669 he became rector of the parish of St George, Botolph Lane, in London; and in 1681 was collated to the prebend of Pancras, in the cathedral of St Paul's. He was likewise chosen master of the Temple, and had the rectory of Therfield, in Hertfordshire. After the Revolution he was suspended from his preferment, for refusing the oaths to William and Mary; but at last he took them, and publicly justified what he had done. In 1691 he was installed as dean of St Paul's. His Vindication of the Doctrine of the Trinity engaged him in a warm controversy with Dr South and others. Bishop Burnet tells us he was "a clear, a polite, and a strong writer; but apt to assume too much to himself, and to treat his adversaries with contempt." He died in 1707. His works are very numerous, among which are, 1. A Discourse concerning the Knowledge of Jesus Christ, against Dr Owen; 2. Several pieces against the Papists, the Socinians, and Dissenters; 3. A Practical Treatise on Death; 4. A Practical Discourse on Providence; 5. A Practical Discourse on the Future Judgment; and many other works.

---

[1] It had the singularity of never winking.

Sherlock, *Dr Thomas*, bishop of London, was the son of the preceding, and was born in 1678. He was educated in Catharine Hall, Cambridge, where he took his degrees, and of which he became master. He was made master of the Temple when very young, on the resignation of his father; and it is remarkable, that this mastership was held by father and son successively for more than seventy years. He was at the head of the opposition against Dr Hoadley, bishop of Bangor, during which contest he published a great number of pieces. He attacked Collins's Grounds and Reasons of the Christian Religion, in a course of six sermons, preached at the Temple Church, which he entitled The Use and Intent of Prophecy in the Several Ages of the World. In 1728, Dr Sherlock was promoted to the bishopric of Bangor, and was translated to Salisbury in 1734. In 1747 he refused the archbishopric of Canterbury, on account of his ill state of health; but recovering in a good degree, he accepted the see of London the following year. On occasion of the earthquakes in 1750, he published an excellent Pastoral Letter to the clergy and inhabitants of London and Westminster, of which it is said there were printed, in quarto five thousand, in octavo twenty thousand, and in duodecimo about thirty thousand, besides pirated editions, of which not less than fifty thousand were supposed to have been sold. Under the weak state of body in which he lay for several years, he revised and published four volumes of Sermons, in octavo, which are particularly admired for their ingenuity and elegance. He died in 1762, worth L.150,000. "His learning," says Dr Nicholls, "was very extensive. God had given him a great and an understanding mind, a quick comprehension, and a solid judgment. These advantages of nature he improved by much industry and application. His skill in the civil and canon law was very considerable; to which he had added such a knowledge of the common law of England as few clergymen attain to. This it was that gave him that influence in all causes where the church was concerned, as knowing precisely what it had to claim from its constitutions and canons, and what from the common law of the land." Dr Nicholls then mentions his constant and exemplary piety, his warm and fervent zeal in preaching the duties and maintaining the doctrines of Christianity, and his large and diffusive munificence and charity; particularly by his having given large sums of money to the corporation of clergymen's sons, to several of the hospitals, and to the society for propagating the gospel in foreign parts, and also bequeathing to Catharine Hall, in Cambridge, the place of his education, his valuable library of books, and his donations for the founding a librarian's place and a scholarship, to the amount of several thousand pounds.

SHERON, a village of Persia, in Irak, fifteen miles east from Kermanshaw.

SHERRIFF of Mecca, the title of the descendants of Mahommed by Hassan Ibn Ali. These are divided into several branches, of which the family of Ali Bunemi, consisting at least of three hundred individuals, enjoy the sole right to the throne of Mecca. The Ali Bunemi are again subdivided into two subordinate branches, Darii Sajid and Darii Barkad, of whom sometimes the one, sometimes the other, have given sovereigns to Mecca and Medina, when these were separate states.

SHETLAND. See Zetland.

SHEVAGUNGA, a polygar town and district of Southern India, in the province of the Carnatic, and district of Little Marawar. This country, according to the custom of the Nairs, was ruled by females until about sixty years ago, when the government was usurped by two brothers of low caste. They were expelled by the nabob of Arcot, with the aid of the British troops, who afterwards reinstated them. They were again expelled, and being pursued and captured by the British, they were condemned and executed, and the country given to a relation of the former female sovereigns. Long. of the town 78. 30. E. Lat. 9. 54. N.

SHEVAGURRY, a town of the south of India, in the district of Tinnevelly, a hundred miles north from Cape Comorin. Long. 77. 32. E. Lat. 9. 23. N.

SHEVELPATORE, a town of the south of India, in the province of the Carnatic, 110 miles north from Cape Comorin. Long. 77. 43. E. Lat. 9. 31. N.

SHIELD, an ancient weapon of defence, in the form of a light buckler, borne on the arm to fend off lances, darts, and other weapons. The form of the shield is represented by the escutcheon in coats of arms. The shield was that part of the ancient armour on which the persons of distinction in the field of battle always had their arms painted; and most of the words used at this time to express the space that holds the arms of families are derived from the Latin word *scutum*. The French *escu* and *escussion*, and the English word *escutcheon* or *scutcheon*, are evidently from this origin; and the Italian *scudo* signifies both the shield of arms and that used in war. The Latin name *clypeus*, for the same thing, seems also to be derived from the Greek word *γλυφειν, to engrave;* and it had this name from the several figures engraved on it, as marks of distinction of the person who wore it.

The shield in war, among the Greeks and Romans, was not only useful in defence, but it was also a badge of honour to the wearer; and he who returned from battle without it was always treated afterwards with infamy. People have at all times thought this honourable piece of the armour the properest place to engrave or figure on the signs of dignity of the possessor of it; and hence, when arms came to be painted for families in aftertimes, the heralds always chose to represent them upon the figure of a shield, but with several exterior additions and ornaments, as the helmet, supporters, and the rest.

The form of the shield has not only been found different in various nations, but even the people of the same nation, at different times, have varied its form extremely; and among several nations there have been shields of several forms and sizes in use, at the same period of time, and suited to different occasions. The most ancient and universal form of shields, in the earlier ages, seems to have been the triangular. This we see instances of in all the monuments and gems of antiquity. Our own early monuments show it to have been the most antique shape also with us, and the heralds have found it the most convenient for their purposes, when they had any odd number of figures to represent; as if three, then two in the broad bottom part, and one in the narrow upper end, it held them very well; or if five, they stood as conveniently, as three below and two above. The other form of a shield, now universally used, is square, rounded, and pointed at the bottom. This is taken from the figure of the Samnitic shield used by the Romans, and since copied very generally by the English, French, and Germans.

The Spaniards and Portuguese have the like general form of shields, but they are round at the bottom, without the point; and the Germans, besides the Samnite shield, Shields, North.

have two others pretty much in use. These are, first, the bulging shield, distinguished by its swelling or bulging out at the flanks; and, secondly, the indented shield, or shield chancree, which has a number of notches and indentings all round its sides. The use of the ancient shield of this form was, that the notches served to rest the lance upon, that it might be firm while it gave the thrust; but this form being less proper for the receiving armorial figures, the two former have been much more used in the heraldry of that nation.

Besides this different form of the shields in heraldry, we find them also often distinguished by their different positions, some of them standing erect, and others slanting various ways and in different degrees. This the heralds express by the word *pendant*, "hanging," because they seem to be hung up, not by the centre, but by the right or left corner. The French call these *ecu pendant*, and the common antique triangular ones *ecu ancien*. The Italians call it *scuto pendente;* and the reason given for exhibiting the shield in these figures in heraldry is, that in the ancient tilts and tournaments, they who were to joust at these military exercises were obliged to hang their shields, with their armories, or coats of arms, on them, out at the windows and balconies of the houses near the place, or upon trees, pavilions, or the barriers of the ground, if the exercise was to be performed in the field.

Those who were to fight on foot, according to Columbier, had their shields hung up by the right corner, and those who were to fight on horseback had theirs hung up by the left. This position of the shields in heraldry is called *couche* by some writers, though by the generality *pendant.*

It was very frequent in all parts of Europe, in arms given between the eleventh and fourteenth centuries; but it is to be observed that the hanging by the left corner, as it was the token of the owner's being to fight on horseback, so it was esteemed the most honourable and noble situation; and all the pendant shields of the sons of the royal family of Scotland and England, and of our nobility, at the time, are represented thus hanging from the left corner. The hanging from this corner was a token of the owner's being of noble birth, and having fought in the tournaments before; but no sovereign ever had a shield pendant any way, but always erect, as they never formally entered the lists of the tournament.

The Italians generally have their shields of arms of an oval form. This seems to be done in imitation of those of the popes and other dignified clergy; but their herald, Petro Sancto, seems to regret the use of this figure of the shield, as an innovation brought in by the painters and engravers, as most convenient for holding the figures, but derogatory to the honour of the possessor, as not representing either antiquity or honours won in war, but rather the honours of some citizen or person of learning. Some have carried it so far as to say, that those who either have no ancient title to nobility, or who have sullied it by any unworthy action, cannot any longer wear their arms in shields properly figured, but are obliged to have them painted in an oval or round shield. In Flanders, where this author lived, the round and oval shields are in the disrepute he speaks of; but in Italy, besides the popes and dignified prelates, many of the first families of the laity have them.

The secular princes, in many other countries, also retain this form of the shield, as the most ancient and truly expressive of the Roman clypeus.

Shield, in *Heraldry*, the escutcheon or field on which the bearings of coats of arms are placed.

Shield Cape, a low point on the coast of New Holland, in the Gulf of Carpentaria, which projects six miles into the sea. Long. 136. 23. E. Lat. 13. 19. N.

SHIELDS, North, a township of the parish of Tynemouth, in the county of Northumberland, 233 miles from London and eight from Newcastle, situated on the north bank of the Tyne. It has gradually grown from a dirty fishing village to a town of great extent and wealth, from the coal trade. The population amounted in 1831 to 6744.

Shields, *South*, a township of the parish of Jarrow, in the county of Durham. It stands on the river Tyne, opposite to North Shields, and, like it, has risen chiefly from the coal trade, but has, besides, extensive salt-works. There are also large establishments for making glass, and for ship-building. It consists for the most part of one street, extending nearly two miles along the bank of the river. The population amounted in 1821 to 8885, and in 1831 to 9682.

SHIFFNAL, a town of the hundred of Brimstrey, in the county of Salop, 143 miles from London. It is a small place, of no trade except that arising from its being on the great post-road from London to Holyhead. There is a market on Friday. The population amounted in 1821 to 4411, and in 1831 to 4779.

SHIJASHROTAN, one of the Kurile Islands, at the eastern extremity of Asiatic Russia, in the ocean south of Kamtschatka. Long. 154. 39. E. Lat. 49. 15. N.

SHILLING, an English silver coin, equal to twelve pence, or the twentieth part of a pound.

Freherus derives the Saxon *scilling*, whence our shilling, from a corruption of *siliqua;* proving the derivation by several texts of law, and, among others, by the twenty-sixth law, *De annuis legatis*. Skinner deduces it from the Saxon *scild*, "shield," by reason of the escutcheon of arms which it has upon it.

Bishop Hooper derives it from the Arabic *scheele*, signifying *a weight;* but others, with greater probability, deduce it from the Latin *sicilicus*, which signified in that language a quarter of an ounce, or the forty-eighth part of a Roman pound. In confirmation of this etymology, it is alleged that the shilling kept its original signification, and bore the same proportion to the Saxon pound as sicilicus did to the Roman and the Greek, being exactly the forty-eighth part of the Saxon pound.

However, the Saxon law reckons the pound in the round number at fifty shillings, but they really coined out of it only forty-eight. The value of the shilling was fivepence, but it was reduced to fourpence above a century before the Conquest; for several of the Saxon laws, made in Athelstan's reign, oblige us to take this estimate. Thus it continued to the Norman times, as one of the Conqueror's laws sufficiently ascertains; and it seems to have been the common coin by which the English payments were adjusted. After the Conquest, the French *solidus* of twelvepence, which was in use among the Normans, was called by the English name of shilling; and the Saxon shilling of fourpence took a Norman name, and was called the *groat*, or great coin, because it was the largest English coin then known in England.

It was the opinion of Bishops Fleetwood and Gibson, and of the antiquaries in general, that, though the method of reckoning by pounds, marks, and shillings, as well as by pence and farthings, had been in constant use even from the Saxon times, long before the Norman conquest, there was never such a coin in England as either a pound or a mark, nor any shilling, till the year 1504 or 1505, when a few silver shillings or twelvepences were coined, which have long since been solely confined to the cabinets of collectors.

Mr Clarke combats this opinion, alleging that some coins mentioned by Mr Folkes, under Edward I. were probably Saxon shillings new minted, and that Archbishop Ælfric expressly says that the Saxons had three names for their money: mancuses, shillings, and pennies. He also urges the different value of the Saxon shilling at different times, and its uniform proportion to the pound, as an argument that their shilling was a coin; and the testimony of the Saxon gospels, in which the word we have translated *pieces of silver* is rendered *shillings*, which, he says, they would hardly have done if there had been no such coin as a shilling then in use. Accordingly the Saxons expressed their shilling in Latin by *siclus* and *argenteus*. He further adds, that the Saxon shilling was never expressed by *solidus* till after the Norman settlements in England; and howsoever it altered during the long period that elapsed from the Conquest to the time of Henry VII. it was the most constant denomination of money in all payments, though it was then only a species of account, or the twentieth part of the pound sterling; and when it was again revived as a coin, it lessened gradually as the pound sterling lessened, from the 28th of Edward III. to the 43d of Elizabeth.

In the year 1560 there was a peculiar sort of shilling struck in Ireland, of the value of ninepence English, which passed in Ireland for twelvepence. The motto on the reverse was, *posui Deum adjutorem meum*. Eighty-two of these shillings, according to Malynes, went to the pound. They weighed therefore twenty grains one fourth each, which is somewhat heavier in proportion than the English shilling of that time, sixty-two of which went to the pound, each weighing ninety-two grains seven eighths; and the Irish shilling being valued at the Tower at ninepence English, that is, one fourth part less than the English shilling, it should therefore proportionally weigh one fourth part less, and its full weight be somewhat more than sixty-two grains. But some of them found at this time, though much worn, weighed sixty-nine grains. In 1598, five different pieces of money of this kind were struck in England for the service of the kingdom of Ireland. These were shillings to be current in Ireland at twelvepence each, half shillings to be current at sixpence, and quarter shillings at threepence. Pennies and halfpennies were also struck of the same kind, and sent over for the payment of the army in Ireland. The money thus coined was of a very base mixture of copper and silver; and two years after there were more pieces of the same kinds struck for the same service, which were still worse; the former being three ounces of silver to nine ounces of copper, and the latter only two ounces eighteen pennyweights to nine ounces two pennyweights of the alloy.

The Dutch, Flemish, and Germans, have likewise their shilling, called *schelin*, *schilling*, and *scalin*; but these not being of the same weight or fineness with the English shilling, are not current at the same value. The English shilling is worth about twenty-three French sols; those of Holland and Germany about eleven sols and a half; those of Flanders about nine. The Dutch shillings are also called *sols de gros*, because equal to twelve gros. The Danes have copper shillings worth about one fourth of a farthing sterling.

SHILOH is a term famous among interpreters and commentators upon Scripture. It is found (Gen. xlix. 10) to denote the Messiah. The patriarch Jacob foretells his coming in these words: "The sceptre shall not depart from Judah, nor a lawgiver from between his feet, until Shiloh come; and unto him shall the gathering of the people be." The Hebrew text reads, ער בי יבא שלה, *until Shiloh come*. All Christian commentators agree that this word ought to be understood of the Messiah, or Jesus Christ; but all are not agreed about its literal and grammatical signification. St Jerome, who translates it by *Qui mittendus est*, manifestly reads *Shiloach* "sent," instead of *Shiloh*. The Septuagint have it 'Εως ἀν ἔλθη τα ἀποκειμενα ἀυτω; or Εὼς ἀν ἔλθη ὡ ἀποκειται, as if they had read שלן instead of שלה, that is, "Until the coming of him to whom it is reserved;" or "Till we see arrive that which is reserved for him."

It must be owned, that the signification of the Hebrew word Shiloh is not well known. Some translate, "the sceptre shall not depart from Judah, till he comes to whom it belongs;" שלה or שלי instead of לי אלן. Others render it, "till the coming of the peace-maker," or "the pacific;" or, "of prosperity," שלה, *prosperatus est*. Others, again, "till the birth of him who shall be born of a woman that shall conceive without the knowledge of a man," שיל or שליא *secundina, fluxus;* otherwise, "the sceptre shall not depart from Judah, till its end, its ruin; till the downfall of the kingdom of the Jews," שאל or שלה, *it has ceased, it has finished*. Some rabbin have taken the name Siloh or Shiloh as if it signified the city of this name in Palestine: "The sceptre shall not be taken away from Judah till it comes to Shiloh; till it shall be taken from him to be given to Saul at Shiloh." But in what part of Scripture is it said that Saul was acknowledged as king or consecrated at Shiloh? If we would understand it of Jeroboam the son of Nebat, the matter is still as uncertain. The Scripture mentions no assembly at Shiloh that admitted him as king. A more modern author derives Shiloh from שלה, *fatigare*, which sometimes signifies *to be weary*, or *to suffer;* "till his labours, his sufferings, his passion, shall happen."

But, not to amuse ourselves about seeking out the grammatical signification of Shiloh, it is sufficient for us to show, that the ancient Jews are in this matter agreed with the Christians. They acknowledge that this word stands for the *Messiah the King*. It is thus that the paraphrasts Onkelos and Jonathan, that the ancient Hebrew commentaries upon Genesis, and that the Talmudists themselves, explain it. If Jesus Christ and his apostles did not make use of this passage to prove the coming of the Messiah, it was because then the completion of this prophecy was not sufficiently manifest. The sceptre still continued among the Jews; they had still kings of their own nation in the persons of the Herods; but soon afterwards the sceptre was entirely taken away from them, and has never since been restored to them.

The Jews seek in vain to put forced meanings upon this prophecy of Jacob, saying, for example, that the sceptre intimates the dominion of strangers, to which they had been in subjection, or the hope of seeing one day the sceptre or supreme power settled again among themselves. It is easy to perceive that all this is contrived to deliver themselves out of perplexity. In vain, likewise, they take refuge in certain princes of the captivity, whom they pretend to have maintained beyond the Euphrates, exercising an authority over their nation little differing from absolute, and being of the race of David. This pretended succession of princes is perfectly chimerical; and though at certain times they could show a succession, it continued but a short time; and their authority was too obscure, and too much limited, to be the object of a prophecy so remarkable as this was.

SHINAAS, a small seaport on the Persian Gulf, situated between the town of Sinja and Cape Bastana.

SHINGLES, in building, small pieces of wood, or quartered oaken boards sawn to a certain scantling, or, as is more usual, cleft to about an inch thick at one end, and made like wedges, four or five inches in breadth and eight or nine inches in length.

Shingles are used instead of tiles or slates, especially for churches and steeples. This covering, however, is dear; yet, while tiles are very scarce, and a light covering is required, it is preferable to thatch; and where they are made of good oak, cleft, and not sawed, and well seasoned in water and the sun, they make a sure, light, and durable covering.

SHIP, a general name for all large vessels, particularly those equipped with three masts and a bowsprit; the masts being composed of a lower mast, top-mast, and top-gallant-mast, and each of these being provided with yards, sails, and the like. Ships, in general, are either employed for war or merchandise.

SHIP-BUILDING.

Introductory Observations.

Introduction.

Aphorism of Sir Walter Raleigh.

That profound thinker, Sir Walter Raleigh, has left this aphorism on record, "Whosoever commands the sea commands the trade; whosoever commands the trade of the world commands the riches of the world, and consequently the world itself." The time has passed by in which the command of the seas either can or ought to be maintained according to the spirit in which Sir Walter Raleigh framed this aphorism. Still the principle it is intended to enforce is as essential to the wellbeing of England now as it was then. We rejoice at the liberality of international communication, and of the political relations which distinguish the present age. We do more; we fervently hope that the same spirit may increase, even until all national distinctions and national divisions shall vanish before it. Yet we cannot but remember that it is with nations as with individuals. Interests may clash, quarrels may arise, and the friendships and the kindly feelings of to-day may be succeeded by the dissensions and the feuds of to-morrow; and therefore, even in the midst of a peace unexampled for its heartiness, and for the good faith which apparently pervades the councils of the nations of Europe, we cannot with wisdom neglect those means of defence which have hitherto preserved our land inviolate.

Continental naval policy.

The aphorism of Sir Walter Raleigh is of general application; but to an insular power, and which can only be reckoned of secondary rank in the scale of nations, in as far as size and population only are involved, naval pre-eminence is essential to its independence. An eminent statesman has lately most forcibly urged upon the continental nations of Europe this all-important fact, that the command of the seas, when vested in an insular power, gives her despotic authority over the nations of the earth, because she is herself invulnerable. He proceeds from this position to the conclusion, that the interest of Europe renders it imperative, that since the sceptre of the seas is at present held by an insular power, it should be wrested from her grasp, and bestowed on another, which, by being continental, must be vulnerable on her land frontier, and cannot therefore be despotic in her naval rule. Thus far does the continental writer pursue the argument, because thus far only are the interests of continental nations concerned; but for us there is yet another induction to be made; it is this: The same cause which invests an insular power with universal dominion as long as she can maintain the sovereignty of the seas, must divest her of all power when that sovereignty is lost; she falls at once from her high pre-eminence; first on the list of nations, to rank among the secondary powers; for the sea, her impregnable fortress in the one case, becomes a barrier to her enterprise in the other. It would be no difficult task to prove, from the history of Europe, that the influence of England among the nations has increased or diminished in proportion as her navy has been fostered or neglected.

It is strange, that with such a tremendous stake at issue as national independence, it should be possible to write, and to write with truth, that there have been periods in our history, during which the navy and the naval resources of this country have been suffered to decline. The naval sceptre has more than once trembled in our grasp: we trust the time is far distant in which we may again wield it in anger; but should that time ever arrive, the struggle must be desperate, because the powers of Europe have been taught that our naval pre-eminence places their destinies in our hands.

Introdu- tion.

England has few no scien fic treat on naval chitec

In connection with the occasional neglect of her naval resources, is another strange anomaly, namely, that England has less than any other maritime power encouraged the application of the exact sciences to naval architecture. She has not to this day one original truly scientific treatise on the subject in her language; and, passing by some few papers and tracts of modern times, she can only cite the writings of uneducated and unlearned men, as Mungo Murray, Hutchinson, and Stalkart, against those of such names as the Bernoullis, Euler, Chapman, Don Juan, Bouguer, Clairbois, Romme, and a host of others. The establishment of a school for naval architecture at Portsmouth has been directly and indirectly the means of diffusing much knowledge on this important subject, and the result has been a very considerable improvement in our ships of war, so that latterly they may perhaps fairly claim equality with those of other nations. It is perhaps principally in her merchant-shipping that England now suffers from this neglect of science.

It is a recognised principle that demand creates supply, and therefore we may presume that in England there has been no demand, such as would encourage men of science to furnish forth the supply. It is not irrelevant to the subject of this article to trace out the causes which have operated to this effect; they must be made known to be removed; and it is in vain to urge improvement if there be any insuperable bar to its progress in operation. And again, it cannot be irrelevant, in an article on a national subject, and in a national work, to pursue the inquiry to its end, the more so as we believe the task will lead us to the conclusion, that, however harmless hitherto this state of apathy to improvement may have been, the time has now arrived when its continuance will be dangerous to our naval pre-eminence; for through it, to quote again from Sir Walter Raleigh, we may lose "the command of the trade of the world, the command of the riches of the world, and consequently of the world itself."

English predilec tion for sea of e origin.

The predilection for the sea, and for a seafaring life, which is proverbially general throughout the population of England, may most probably be traced to an early period in our history, when, after the Norman conquest, for a long period of years, both shores of the narrow seas were under one rule, and the nobles of the land had possessions on either side of the Channel. This, and the constant intercourse kept up between England and her armies during the long subsequent wars, must have trained a hardy race of seamen, and have made passages by sea familiar to the entire population. The impression once given, the facilities afforded for maritime adventure, by the great comparative extent of our coast, and its numberless harbours, were quite sufficient to maintain it. Our insular situation will not alone account for our love of naval enterprise; otherwise a similar predisposition would be general with the inhabitants of islands, whereas we find a most remarkable instance to the contrary in Ireland, a country possessed of even more maritime advantages than England; with a more indented, and therefore a more favourable coast, with proportionally larger rivers, and with many lakes of great magnitude in the interior. This predilection of our population for the sea has hitherto enabled us most triumphantly to maintain our naval pre-eminence, even against the known and acknowledged advantages of superior ships; for it is universally admitted that the naval powers of the Continent have, throughout their struggles with us, been possessed of superior classes of vessels, in many respects, to those which we have employed against them.

It is a question for serious consideration, whether we are sure, throughout the future, to be able to contend with equal success should we labour under similar disadvantages; or whether there are causes now in operation which may render a favourable result questionable?

In pursuing our inquiry into the present state of the theory of ships, and particularly as it is applied to our mercantile navy, we shall arrive at an answer to this question. It certainly does not necessarily follow, that because our vessels of war have been inferior to those of other nations, our merchant-shipping should be in a similar position with respect to their mercantile navies.

The merchant princes of England, with their boundless wealth, proverbial generosity, and persevering enterprise, might surely have attracted the attention of men of science to the improvement of their argosies. That they have not done so is indisputable: the startling fact, that one ship and a half is the average daily loss registered on the books at Lloyd's, appears as a sad corroboration of the acknowledged truth, that the mercantile navy of England is the least speedy and the most unsafe that belongs to a civilized nation. Several causes have combined to produce this result, and to check any improvement in our merchant-ships. These it will be our object to explain.

During the late long war, when our fleets swept the commerce of the other nations from the seas, almost the whole traffic of the world was in our hands, and the carrying trade was shared only by the Americans, their neutrality obtaining for them the same advantages that we commanded by our power; but at the peace the seas were again free to the ships of all nations, and that which had been for a long series of years almost a monopoly, was thrown open to competition. It might naturally be inferred that this would operate injuriously to us; yet the question cannot but arise, why, with all the advantages of possession of the ground, of connection, and of stock, we have been, and still continue to be, supplanted by other maritime nations? We have not only lost much of the carrying trade for foreign merchants, but even English merchants find it for their interest, as individuals, to employ a great proportion of foreign shipping, to such an extent indeed, that nearly one half of the commerce on our western coast is carried on in American vessels. It may be urged against these statements, that the statistics of our mercantile navy show an increase in its numerical strength. This may be admitted, and the force of the argument remain the same; for it is not founded on its positive increase or decrease, but on its relative increase compared with that of the mercantile navies of other nations.

That there should have been a diminution in the demand for our shipping at the conclusion of the war, is a necessary consequence of the many causes of the employment of ships which belong only to a state of war; besides which, as in time of peace the delays occasioned by waiting for convoy are avoided, the time expended in the voyages is shorter, and therefore a less number of ships is required to perform the same quantity of work. We have, however, suffered more than the proportion due to these considerations, which, it should be remembered, must also, in a lesser degree, have operated to check the progress of the American mercantile navy; however, it is this navy which is principally supplanting ours. We cannot evade the conclusion, that the reason for this must be found in the inefficiency and inadequacy of the ships themselves, and that the absence of all improvement in our mercantile navy has placed it in this disadvantageous position.

During the war, almost the only colonial supplies which could reach the continental powers were those plundered by their privateers from the English merchant. The only safety to the English merchant-ship was in sailing in large convoys, in which the velocity of the whole fleet was necessarily regulated by that of the worst sailer. It was therefore of far more importance to the merchant who had few opportunities for adventure, to choose those ships which would carry a larger quantity than those which were possessed of a quality, velocity, of which they could not avail themselves. This operated as an effectual bar to all improvement in the forms of our mercantile shipping, for it caused the absurdities of the late law for tonnage to remain unnoticed for a series of years; and when at length their injurious tendency was perceived, it was not until they had become so completely identified in men's minds with ships themselves, that years more were suffered to elapse before it was clearly made manifest, that the cause of the inferiority of the shipping was the absurdity of the law. Years more must yet elapse before the mercantile navy of Britain can recover from the state to which these laws have reduced it.

Introduction.

Tonnage laws.

Their injurious operation.

American ships sailed singly.

While English merchant-ships were restricted to sailing in convoys, the neutrality of the Americans enabled their vessels to sail singly, and consequently it became immediately desirable to attain the greatest velocity which was consistent with a due portion of the other requisite qualities for a merchant-ship; there was therefore virtually a premium on improvement. Thus the peace found America in possession of an immense commercial navy, which, on an average, could perform its passages in one third less time than our own; and although this is necessarily attained by some sacrifice of capacity, the result has shown the sacrifice to have been judicious. The peace also found America in possession of ship-builders who had made the improvement of the qualities of ships their study. She therefore was not only in possession of a better mercantile navy, with which to compete with us, but she had also the vantage-ground of superior knowledge, and a far more extended experience, from which to start for the future competition. What wonder, then, that we have failed in the contest? The wonder should rather be, that we are not wholly driven from the field. Similar injurious causes operated against the English shipping in comparison with that of several of the maritime powers. Convoy was no safety to their ships of traffic, since their ships of war found no safety for themselves. The only chance for escaping our cruisers lay in sailing singly, as less likely to attract observation, and in trusting to their velocity if observed; besides which, the northern nations of Europe have long been possessed of a very superior class of mercantile shipping, the result partly of the advanced state of the knowledge of the science of naval architecture among them, and partly also of this custom of sailing singly on long voyages, even amidst all the dangers of war. It cannot be a matter of astonishment, therefore, that when the seas were once more open to ships of all nations, the foreign merchants, whom absence of commerce had impoverished, should choose those which would the soonest allow of a return of capital, and at the same time diminish the risk of its loss; for it must be remembered, that the safety of a ship is not only dependent on her powers as a sea-boat, but is in inverse proportion to the time she is exposed to the dangers of the seas. Again, if the foreign merchant thus preferred the foreign ship to the British, surely that competition, which is the very spirit of commercial enterprise, must of necessity have impelled the British merchant to pursue the same course; for it could not be a matter of indifference to him whether his goods should be the first in the market, or should arrive when that market was glutted.

Convoy no safety to foreign ships.

Present tonnage law.

The present modification of the tonnage laws is comparatively harmless, but the leaven of the old law remains. England possesses upwards of two millions and a half of tonnage in inferior shipping; and the merchant-builders of Britain, reared under the baneful influence of that law, are, with a few honourable exceptions, unequal to the task of competition with the more educated and more practised foreigner. The theory of ships is, even by those who are the most instructed in its principles, yet considered in its infancy; it

Difficulty of the study of the theory of ships.

can only be matured by a free and impartial encouragement of the application of the exact sciences to the improvement of naval architecture, and by the total abolition of all laws which can, directly or indirectly, limit the aspirings of the merchant-builders of England in their competition with foreigners. The writer of this article believes that England scarcely ever committed a greater error than when she first determined the existence of a law for levying duties according to tonnage.

Error in having restrictions on ship-building.

We may here advert to a most striking example of the effects of the removal of this check, in the matchless excellence of the yachts of England, and may therefore not unfairly presume, that the same skill which has already exalted one class of vessels beyond competition, might, under similar circumstances, attain the same comparative excellence for another, and that our merchant-ships may yet become as unrivalled as are our yachts. Be the law of tonnage founded on weight, on bulk, or on dimensions, in each and every case it operates as a check to the most important manufacture of the country. There is evidently nothing so essential to England as that she should possess a large maritime population; and this can only be insured by the preponderance of her mercantile navy, which, again, must in future be completely dependent on the qualities of the ships that compose it.

Ships to train seamen the paramount want of England.

It is obvious, that while the effects of a long, and solid, and, we believe, hearty peace, amongst the civilized nations of the world, are to increase the wealth of all other nations as well as our own, and with their wealth to increase their shipping, it becomes a serious national duty on the part of our rulers to frame such laws as may insure to us the vantage-ground we possessed when peace enabled all alike to start in the race of improvement. That we may have free exercise for our skill, capital, and enterprise, we must not be cramped by absurd laws as to the tonnage and sailing regulations of our ships. These impediments should evidently be removed, in order to place us at least upon equal terms with our competitors.

We do not pretend to arrogate to ourselves that command of the seas which was intended by Sir Walter Raleigh. The days when fleets were bound to lower topsails at the bidding of a single pennant have, happily for the wellbeing of mankind, long passed away. But we do say that the end and object of all British policy should be to insure such preponderance on the seas, that if, amidst the changes which we almost daily see occurring, and which make the possible advent of war no speculative imagining, one should arise to plunge Europe again into strife, England may not be found wanting in practised seamen. This, we believe, can only be assured by her possessing a mercantile navy, composed of ships the good qualities of which will insure for them a large proportionate share of the carrying trade of the world. In short, we believe, that, to insure for our military navy, in times of war, successes triumphant as heretofore over every sea, it is essential that our mercantile navy should, in these times of peace, crowd every port.

It is in order to advance this cause that we shall endeavour to set in a clear point of view the several difficulties which occur in the study of naval architecture; and we feel no doubt whatever, that if the principles of construction which we shall endeavour to explain be duly attended to, and the study followed up in earnest, the results will prove their correctness, and that the mercantile navy of England will become as unrivalled in its excellencies as are almost all the other productions of the skill, talent, and enterprise of this favoured land.

Rise and Progress of Naval Architecture among the Nations of Antiquity.

Charnock's chronological divisions.

In tracing the progress of naval architecture among the nations of antiquity, in order to connect it with its advance in more modern times, we shall cite the chronological divisions adopted by that indefatigable investigator Charnock, in his valuable History of Marine Architecture, because they present a very succinct idea of the probable rise, progress, decline, and revival of the art, and therefore offer a valuable guide for investigation. It would not be consistent with the purpose of this article to enter into the detail that would be necessary to ascertain the state of naval architecture during the periods embraced in each of the sections he has assigned to this subject. We shall confine ourselves to the statement of some few facts, collected from various authors, in illustration of the probable size and nature of the shipping of the ancient world. We shall also endeavour to trace what little is known of the rude vessels which, during the darkness of the middle ages, bore the marauders of the northern nations on their predatory excursions; in which they carried desolation and misery throughout the coasts of Europe, and, while they rooted out the last relics of ancient civilization, laid the foundations of empires which were destined, in their turn, to civilize the world. With Charnock's sixth section, inclusive perhaps of some few years at the close of his fifth, the naval history of Britain commences; and during the period embraced between that date and the present time we must gradually become more diffuse in our detail.

Charnock divides maritime history into seven sections. The first comprehends the time previous to the foundation of Rome, until which, he says, all history is founded on surmise. The second section comprises a period somewhat less obscure, in which the collateral testimony of various authors may be examined and compared; and therefore there certainly appears less difficulty in ascertaining facts. It extends from the foundation of Rome to the destruction of her rival Carthage. The termination of the third is at the conversion of the republic into an empire, an era when the want of naval enemies to contend with rendered the maintenance of a fleet, as connected with the prosperity and safety of the state, a consideration not only of secondary, but immaterial consequence. The death of Charlemagne ends the fourth epoch. The fifth extends from this period to the discovery of the mariner's compass. The sixth ends with the discovery of cannon; and their adaptation to naval warfare commences the seventh epoch.

Ancient shipping principally propelled by oars.

It will avoid much useless repetition if we premise our investigations on the state of ship-building among the nations of antiquity, by the observation that their fleets, whether for war or for commerce, appear to have consisted almost entirely of vessels whose principal mode of propulsion was by the use of oars. It would be foreign to the object of the present article to enter into the useless and perplexing, though most enticing question, as to how those oars were applied in the trireme, quadrireme, and quinquireme, nay, on the authority of Plutarch, even to the extent of fifty distinct banks of oars. It is possible to conceive many methods in which the benches of the biremes, and even of the triremes, may have been disposed, which would enable the oars to be plied with ease and advantage. But the vast combination implied by the fifty banks of the galley of Ptolemy Philopater has as yet received no solution, unless it may be that suggested by Mr Holwell in his Essay on the War Galleys of the Ancients, which we shall therefore, in the absence of all certain data, adopt. He imagines that the banks of oars must have been arranged obliquely up the sides of the vessel, as many oars in each bank as would admit of the highest being rowed with facility; then each additional bank would only require additional length in the vessel. Thus the galley of Ptolemy Philadelphus might have had forty, and that of Ptolemy Philopater fifty, of these oblique ascents of oars, and yet need not necessarily have been higher out of the water than the ordinary quinquireme. It should be stated, that the triremes seem to have been the limit of practical utility in the disposition of the oars, as they appear to have been most usually adopted for the purposes of war.

ojan r.

In tracing the records of the sizes of vessels, we find, on the authority of Thucydides, that the Grecian flotilla, at the siege of Troy, about 1184 years B. C., consisted of 1200 vessels, the largest of which contained not more than 120, the least fifty people. He also expressly says that they were without decks. These were therefore mere open row-boats or canoes.

rst naval ttle.

A great improvement on these must have been made in the fleets of the Corcyrians and Corinthians, between whom took place the first naval battle on record, and which occurred about 650 years before Christ; because at that time it appears the arrangement of the oars in banks had been introduced.

ils evi- ntly little ed.

We may perhaps infer, from a statement made by Thucydides, that these vessels were not adapted for carrying any large portion of sails, as they evidently had little if any ballast. He says (book i. chap. 50), "The Corinthians, when their enemies fled, staid not to fasten the hulls of the galleys they had sunk unto their own galleys, that so they might tow them after, but made after the men, rowing up and down to kill rather than to take alive." The vessels spoken of as sunk were evidently merely stove in and water-logged.

ventors the tri- mes and inqui- mes.

Herodotus, Thucydides, and Diodorus agree that Aminocles, the "shipwright of Corinth," was the inventor of the trireme, about forty years previous to this battle. The invention of the quinquireme is generally attributed to the Carthaginians.

lamis.

At the battle of Salamis, 480 years B. C., on the authority of Plutarch, the largest Grecian vessels carried only eighteen soldiers, exclusive of the rowers, and those employed in manœuvring the vessels.

eet of ardonius.

In the fleet of Mardonius, crowded as it must have been by a force collected for the purpose of invasion, we find that, on a comparison of the number of ships lost by tempest and the number of men drowned, the average is only sixty-six men to each vessel. This fleet consisted of 1200 galleys, and 2000 hulks (ὁλκαδες) of the "round manner of building."

ssels lf cked.

The whole of the Grecian vessels appear to have been only half-decked; the soldiers were stationed on platforms at each extremity, the middle or waist being left open for the rowers. Cimon, the celebrated Athenian commander, was apparently the first to join these two platforms with an intermediate flat, and thus to form a perfect deck, for the purpose of opposing a stronger armed force to the Persians.

cks in- duced Cimon.

This innovation took place preparatory to the battle of Eurymedon, B. C. 470. These decks were hatches to be removed at pleasure. The quinquiremes appear afterwards to have been always thus fitted, the quadriremes and biremes only occasionally; and all below these in size were open boats.

ips of ght build.

From the rapid preparation of armaments of most imposing force, in as far as numbers of shipping are concerned, and also from the fact of the ease with which the vessels were transported by land, we must infer that they were of but small dimensions, and of very fragile construction; and though occasionally we find that fabrics of large size were constructed, it was evidently, from the gorgeous descriptions which remain of them, more out of ostentation than from any anticipation of their utility.

eet of earchus.

The vessels composing the fleet of Alexander the Great in his Indian expedition, and in which Nearchus performed his celebrated voyage, were row-galleys of such moderate dimensions that, in the course of the voyage, they were frequently hauled on shore; and although we find, by collating the number of vessels and the number of men composing the expedition, that there could not have been more than fifty or sixty men on board each vessel, their accommodations were so poor that the journal takes notice of the inconvenience experienced by the crews from being obliged to remain for two consecutive nights on board. Purchas gives the detail of this voyage of Nearchus, on the authority of Arianus, lib. viii.

Carthaginians.

To pass to the Carthaginians, a people of great commercial enterprise and importance, and who inherited their nautical knowledge from their progenitors the Phœnicians, of whose commercial wealth history, both sacred and profane, gives repeated evidence: Ezekiel (chap. xxvii.) says of Tyre, It is situated at the entry of the sea, is a merchant for many isles; its ship-boards are of fir-trees of Senir, their masts of cedars, their oars of oak of Bashan, their benches of ivory, their sails of fine embroidered linen.

Voyage of Hanno.

We find that the Carthaginians must at a very early period of their history have possessed vessels of considerable magnitude; for in the journal of the much though unjustly disputed voyage of Hanno, which Clark, in his History of Maritime Discovery, places at 350 B. C., but which by some historians is said to have taken place as early as 1000 B. C., sixty ships afforded accommodation for 30,000 souls, including women and children, and this, too, with all the stores and requisites for colonization, which was the main purport of the enterprise. The little we know of the Carthaginians, we know through their implacable foes the Romans; and as the Roman fleets were built after a Carthaginian model, we may pass on to investigate the few certain particulars we can collect of the Roman shipping; though, in doing so, we must not assume that we are in possession of the extent of the state of naval science among the Carthaginians. All that the Romans adopted from them was their war-galley. Their commerce, and consequently their commercial vessels, were alike despised by this predatory state, which then lived almost solely by the sword.

Roman shipping.

Charnock, on the authority of Meibomius, has given the following as the dimensions of the Roman trireme and quadrireme. The triremes were 105 feet long and eleven feet broad. The quadriremes were 125 feet long and thirteen feet broad. The triremes, after the time of Julius Cæsar, were ninety feet long and ten feet broad. These dimensions have a much greater comparative length to breadth than the proportions adopted for the Neapolitan and Maltese galleys of more modern times. In them the length seldom exceeded seven breadths. According to Vossius, who is also one of the most voluminous writers on the subject of the shipping of the ancients, these Neapolitan galleys were capable of performing voyages by the oar of sixty leagues in twenty-four hours; and the distance from Naples to Palermo has been performed in seventeen hours.

Cæsar's account of the size of ships

Cæsar himself gives us a good criterion of the size of the Roman vessels employed by him in the invasion of Britain; for he says that they were so large that they could not approach near enough to the shore for the soldiers to disembark, but that they were obliged, encumbered as they were with their arms, to jump into the water, which was breast high; and that at last the galleys were ordered in between these larger vessels and the shore, to protect the disembarkation.

First Roman fleet.

When we consider the dimensions above quoted for the Roman navy, it does not appear that there is necessarily much exaggeration in the accounts given of the wonderful exertions made by that people to prepare their first maritime force. Sixty days after the axe was laid to the root of the tree, 160 galleys according to some accounts, 100 quinquiremes and twenty biremes according to others, rode at anchor in the sea; the quinquiremes each manned by 300 rowers and 200 soldiers. Polybius states the Roman fleet at the time of the first Punic war to have consisted of 330 ships, each containing 300 rowers and 120 soldiers. If we compare the small number of vessels which the might of Rome put forth at this time, when her very existence depended upon the success of her naval exertions, and then contemplate the enormous numerical force of the fleets of the petty Grecian states, we may form a very correct judgment of the necessarily comparative insignificance of the vessels which composed these more early navies.

Classes of Roman Shipping.

The Roman ships were divided into three classes: the *naves longæ*, or ships of war; the *naves onerariæ*, or ships of burthen; and the *naves liburnæ*, which were ships built expressly for great velocity, and may be supposed to have been used as despatch-boats, and for making passages with important personages. There is repeated evidence to prove that these vessels were invariably built of pine, cedar, or other light woods, excepting about the bows, which were of oak, strongly clamped and strengthened with iron or brass, in order to withstand the shock of opposing vessels; the tactics being comprised in the attempt to sink or damage the enemy's vessel, by violently propelling this armed bow against the weaker broadside of the enemy, or else endeavouring to break and cripple the oars. Oak was first applied to ship-building by the Veneti. This we have on the testimony of Cæsar in his treatise *De Bello Gallico*, lib. iii. cap. 13. Copper or brass was introduced for fastenings, in consequence of the quick corrosion of the iron, about the time of Nero. This is stated on the authority of Vegetius, and also of Athenæus; and Pliny mentions that flax was used for the purpose of caulking the seams of the plank.

Oak first used in ship-building.

Copper.

Caulking.

Exhumation of a Roman vessel.

The following quotation is from Locke's History of Navigation: "Sheathing of ships is a thing in appearance so absolutely new, that scarce any will doubt to assert it altogether a modern invention; yet how vain this notion is, will soon appear. Leo Baptisti Alberti, in his book of Architecture (lib. v. cap. 12), has these words: But Trajan's ship weighed out of the lake of Riccia at this time, while I was compiling this work, where it had lain sunk and neglected for above thirteen hundred years; I observed that the pine and cypress of it had lasted most remarkably. On the outside it was built with double planks, daubed over with Greek pitch, caulked with linen rags; and over all a sheet of lead fastened on with little copper nails. Raphael Volaterranus, in his Geography, says this ship was weighed by the order of Cardinal Prospero Colonna. Here we have caulking and sheathing together, above sixteen hundred years ago; for I suppose no man can doubt that the sheet of lead nailed over the outside with copper nails was sheathing, and that in great perfection, the copper nails being used rather than iron, which, when once rusted in the water, with the working of the ship, soon lose their hold and drop out."

Slight as this sketch may appear of the navies of antiquity, it embraces an outline of almost all that has descended to our times. No portion of ancient history is so imperfect as that which relates to the shipping, and in none necessarily has the historian derived less aid from remains. Even the monumental records here fail him, as the prow alone is sculptured on them.

Progress of Naval Architecture from the Downfall of Rome to the present Time.

Middle ages.

During the many centuries of utter stagnation in all improvement which succeeded the downfall of ancient civilization, it would appear vain to seek for records of the progress in naval architecture. "These were times," says Rymer, in the dedication of the third volume of the Fœdera, "of great struggle and disorder, all Europe over, and the darkest period of times." Although it may be useless to search for records of the improvement of the means of navigation during these ages, when thought appears to have been banished from the earth, and action to have been the only object of man's life, we may undoubtedly expect that, in the countries bordering on the seas, the spirit of naval enterprise would be peculiarly fostered, as congenial to man's habits, or essential to his preservation, during a period of universal aggression, confusion, and migration. The northern regions of the earth, regions which the civilization of the south had deemed uncongenial to man and unfit for his habitation, appear to have teemed, in all their wild and far-spreading districts, with a hardy and an adventurous population, horde after horde of whom poured down from the north-east in irresistible might, and spread desolation and misery throughout Southern and Western Europe; while from the north-west the same wide-spreading desolation swept away all trace of the incipient civilization of Britain and of Gaul. Every sea was ploughed by the fragile barks of the Scandinavian adventurers, and every shore was devastated by their incursions. Denmark, Norway, and Sweden sent their hardy sons to the coasts of the German Ocean, the Channel, the Bay of Biscay, and even to the Mediterranean on the west; while the barbarians of the Sclavonian nations poured down through the Danube and the Borysthenes on the east of Europe, the population of which, rendered feeble by the divisions and dissensions attendant upon the breaking up of the gigantic power of Rome, and enervated by the Sybaritc civilization of the latter days of that empire, perished beneath the arms or bent to the yoke of the hardy progeny of the north. The Saracens wrested from the descendants of the Cæsars the remnant which the Goth and Hun had spared; and Europe became repeopled throughout its limits with a young, a vigorous, and an enterprising population, while the maritime provinces had generally been the spoil of tribes inured to the dangers and delighting in the excitement of maritime adventure.

Northern nations.

Their enterprise.

We cannot but be astonished at the indomitable spirit of enterprise which characterized these rude times. But that, perhaps, which is the most extraordinary feature of the daring that distinguished this period, is to be traced by the results of its naval expeditions, which could not be believed, had they not been established on the most unquestionable evidence; and the whole history of the middle ages, with their revolutions, may be cited in corroboration of them. Still they had such important influence on the state of Western Europe, that, judging of causes by their effects, there must ever remain a doubt of our being in possession of correct information as to the means by which the results we speak of were accomplished. It is not difficult to suppose adventurous men trusting themselves to the mercies of the winds and the waves, and leaving the sterile north to plunder and colonize more favoured climates, of the existence of which their traditions might inform them. But this is not all: there is ample evidence to prove a recurrence of such enterprising voyages, their successful achievement, and the safe return of the adventurers, not only to Norway and the main land, but to Iceland; a remote spot, which might be left, but certainly could not be again repeatedly attained without more knowledge than we are willing to concede to so remote a period.

Their co parative difficulti

The navigator of the present day, accustomed to rely on the almost infallible aid of the compass, the chronometer, and the sextant, would pause ere he dared to commit himself to the boundless expanse of ocean, with no more sure pilotage over its trackless waters than he might chance to find from the appearance of the sun or stars and the flight of birds. And yet we have no record that these Scandinavian sea-kings knew of more certain guides than the sun by day, the stars by night, and such further aid as perchance might be wrested to their purpose, from the varied phenomena of nature; phenomena which may now be unobserved, because not needed.

Voyage Floke.

We read in Purchas's Pilgrims the following account of the voyage of Floke, a Norwegian pirate, made in the early part of the tenth century, from Shetland to Iceland; which he gives on the authority of Arngrim Jonas, an Icelandic

story.

historian. "There was yet no use of the marinrs compasse, wherefore Floco leaving Hietlandia, tooke certayne ravens unto him; and when hee thought hee had sayled a great way, he sent forth one raven, which flying aloft, went backe againe to Hietlandia, which she saw behind. Whereupon Floco perceiving that he was yet neerer to Heitlandia then other countryes, and therefore couragiously going forward, he sent forth another raven, which, because she could see no land, neither before nor behind, light unto the ship again. But, lastly, the third raven was sent forth by Floco, and having for the most part performed his voyage, through the sharpnesse of her quicke sight attayned the land, she speedily flew thither, whose direction Floco following, beheld first the eastern side of the iland."

on ves-
.

The vessels of the Saxon marauders are described by Charnock in the following terms: "The keel of their large flat-bottomed boats was framed of light timber, but the sides and upper works consisted only of wicker, with a covering of strong hides. The Saxon boats drew so little water, that they could easily proceed four score or an hundred miles up the great rivers; the weight was so inconsiderable, that they were transported on waggons from one river to another; and the pirates who had entered the mouth of the Seine or the Rhine might descend with the rapid stream of the Rhone into the Mediterranean."

This description of the skin-covered boats of the northern seas is founded on testimony which cannot be disputed. And, if they were used by the Northmen on their longer voyages, it was probably when they purposed incursions into the interior of the countries they were about to devastate; but that they must have had another and a far superior description of vessel, there can be no reason to doubt.

ral So-
y of
thern
iqua-
s.

The investigations of the Royal Society of Northern Antiquarians at Copenhagen have thrown considerable light on the subject of this early navigation, and of the discoveries of the Scandinavians in the west; and we can no longer suppose that it was in these coracles that frequent voyages were made to Newfoundland, and colonies established there, which it appears proved that there were even as early as the tenth century. But to recur to evidence which is familiar to us.

ulish
eti.

We have the description given by Cæsar of the ships of the Gaulish Veneti. "Their bottoms were somewhat flatter than ours, their prows were very high and erect, as likewise their sterns, to bear the hugeness of the billows and the violence of the tempests. The body of the vessel was entirely of oak. The benches of the rowers were made of strong beams about a foot in breadth, and fastened with iron nails an inch thick. Instead of cables, they secured their anchors with chains of iron; and made use of skins and a sort of thin pliant leather, by way of sails, probably because they imagined that canvass sails were not so proper to bear the violence of tempests, the rage and fury of the winds, and to govern ships of that bulk and burthen. ……Neither could our ships injure them with their beaks, so great was their strength and firmness, nor could we easily throw our darts, because of their height above us, which also was the reason that we found it extremely difficult to grapple the enemy and bring them to close fight." And again, speaking of the manner in which these ships were eventually taken possession of: "They," the Romans, "had provided themselves with long poles, armed with long scythes; with these they laid hold of the enemies' tackle, and drawing off the galley by the extreme force of oars, cut asunder the ropes that fastened the sailyards to the masts; these giving way, the sailyards came down, insomuch that as all the hopes and expectations of the Gauls depended entirely on their sails and rigging, by depriving them of this resource we at the same time rendered their vessels wholly unserviceable."

History.

The account proceeds to state, that many attempted to escape from this unforeseen means of aggression; but that the wind falling, and a perfect calm coming on, they were obliged to remain inactive on the water, and were taken possession of, one after the other, by the simultaneous attack of several Roman galleys. It would appear from this that they were vessels only intended for sailing, and that since oars were used, from the mention made of seats for the rowers, they could have been as very partial accessories to the sails, or probably even only for steering. Another fact is mentioned by Cæsar, that the Veneti sailed from their port to meet the Roman fleet, and several of the vessels escaped to their port from the fleet. This, though not conclusive of the fact of sailing on a wind, is worthy of notice.

Hengist and Horsa.

It is probable that it was ships such as these which brought Hengist and Horsa to England about the middle of the fifth century, since it is recorded that their force, which consisted of 1500 men, found accommodation in only three vessels. It is hardly to be imagined that the coracles or skin-boats of the northern nations were ever of sufficient dimensions to accommodate a force of 500 men, with arms and means of active aggression.

Danish invasions.

In the course of little more than a century from the first invasion of Hengist and Horsa, England became quietly subject to Saxon rule; and the prosperity incidental to a state of peace made her again a fit object of prey to new hordes of northern pirates, the Danes. But it is useless to dwell long on these times of historical doubt and inaccuracy. In the words of Milton, "These bickerings to record, what more worth is it than to chronicle the wars of kites or crows, flocking and fighting in the air."

Dawn of civilization.

At length order once more asserted her right to control men's actions, and out of order the arts and wants of civilization began again to dawn in the newly-formed states which had arisen from the wreck of the empires of antiquity. Man then saw that peace ministered to his comfort, and he turned his thoughts to commerce rather than to the sword, as a means of gratifying his newly-acquired cravings. Thus a long period did not elapse before those seas, which had for centuries been tracked only by the bark of the lawless marauder, bore on their surface the well-freighted craft of the peaceful and industrious merchant.

Rise of Venice.

The earlier irruptions of the northern barbarians into Italy had desolated the Roman province of Venetia, and driven a remnant of its inhabitants to the refuge afforded by the small marshy islands at the extremity of the Adriatic. There they are described by Cassiodorus, who assimilates them to water-fowl, as subsisting on fish, and steeped in poverty, their only manufacture and their only commerce being salt. From such humble beginnings arose the state destined to connect the old world with the new, and to lead the van of modern commercial and maritime enterprise. The mercantile prosperity of Venice diffused its influence throughout the shores of the Mediterranean, which thus became once again the nursery of civilization. For many centuries Venice was the great school for the arts connected with navigation, and her shipwrights and seamen were long the most instructed in Europe. While the northern seas were navigated by the Scandinavian sea-kings, in their rude and frail boats, in quest of plunder or of a home, ships floated on the waters of the Mediterranean bearing the banner of St Mark, which, it is said, were, even as early as the tenth century, of the burthen of 1200 up to 2000 tons. The vessels, however, generally adopted by the Mediterranean states, were either copies or modifications of the ancient galley.

Mediterranean galley.

It is a fact worth notice, that while the continuation of the use of this species of vessel in the comparatively tranquil waters of the Mediterranean fostered the arts of commerce and navigation, its introduction into the northern seas, to which it was ill adapted, appears to have checked, in a most remarkable degree, the maritime enterprise which had hitherto so characterized the population of their coasts. It is even probable that the barrier thus opposed to commerce entailed on the states of Northern and Western Europe centuries of comparative barbarism. Yet this was effected for a wise purpose, by one of the greatest ornaments of the middle ages, Alfred the Great.

Alfred. Alfred was the first ruler of England who clearly understood that the policy of Britain was rather to prevent than to resist invasion; and the by-gone history of his country told him plainly that its military strength was not only insufficient to awe invaders from its shores, but that all the military resources at his command were inadequate to preserve the liberties of his people. He therefore turned the energies of his mighty mind to the task of creating a naval force, which should be more powerful than that of his untiring persecutors the Danes. In this we find that he succeeded; and at length, under the protection of the fleets which his genius had created, he was enabled to establish that frame-work of internal policy and government, from the wisdom of which England has even to this day benefited. It is historically certain that Alfred himself superintended the formation of his fleet, and that he gave the design of vessels to be superior to those of the Danes.

His ships. We find that these vessels were galleys, generally rowed with forty oars, some even with sixty, on each side; and that they were twice as long, deeper, nimbler, and less "wavy" or rolling, than the ships of the Danes. The information on this subject is obtained by Selden, from a Saxon chronicle of the time of Alfred, which is in the Cottonian Library.

Reasons for their introduction. It should be remembered, that when Alfred thus introduced the Mediterranean galley into these northern seas, his object was not so much to form a vessel adapted for the purpose of navigating those seas, as to obtain one which would afford space for a large force of fighting men. For this the galley was admirably qualified; and indeed it maintained its place as the appropriate ship for the purposes of war, until the invention of cannon rendered other arrangements necessary.

Their success. The immunity which it insured from the attacks of the Danish marauders, caused its general adoption along the coasts hitherto open to their incursions, on all of which it thus superseded the sailing vessels that we have already described; and we shall find that voyages which, until its introduction, were boldly and successfully achieved, became of rare occurrence and of hazardous issue during the subsequent ages, until the galleys once again gave place to sailing vessels. It also gradually checked the enterprise of the Northmen, by the curb which it placed upon their successes.

Saxon rule. It is not our purpose to give more than a slight sketch of the naval history of Britain through the line of her Saxon princes; for we can discover little data on which to found any speculation even, as to the progress of naval architecture during these ages. We know that the galley of the Mediterranean continued to be used for the defence of the coasts; and the policy of Alfred appears to have been well understood by many of his successors,—that England only enjoyed peace from invasion when her fleets were powerful enough to repel it from her shores. We are also led to suppose that the use of sailing vessels was not wholly abandoned; for in the reign of Athelstan, the third in descent from Alfred, as we read in Hackluyt, it was decreed, that "if a marchant so thrived, that he passed thrise over the wide seas of his owne craft, he was thenceforth a Theins' right worthie."

Mercantile shipping. This establishes two rather interesting facts; one is, that at so early a period of our history there were merchants of importance enough to engage in such a traffic; and the other is, that from the richness of the reward held out to successful enterprise, we are enabled to estimate the difficulty of the task assigned. We may assume that these long voyages were made in ships more adapted for the purpose than galleys; in fact, in the vessels which the galleys had been intended to supersede. But the spirit of maritime enterprise had, as we have said, evidently received a check, since we see that one of the highest rewards in the power of the monarch to bestow was held out to the merchant, as an incitement to an adventure, which the vague hope of plunder would alone have been sufficient to induce that merchant's progenitors to attempt, and successfully perform. However, it is probable that at no time was the art of navigating vessels, which depended principally, although perhaps not wholly, upon their sails, lost in the northern seas. Gibbon says, that at the early crusades the vessels of the "Northmanni et Gothi" (the Norwegians and Danes) differed from those of the other powers, among all of whom the ships partook of the character of the Mediterranean galley. These northern crusaders are described by him as navigating "*navibus rotundis*, that is to say, ships infinitely shorter in proportion to their length than galleys." This was not later than the beginning of the twelfth century, and therefore not so far removed from the periods in question as to render the inference we wish to deduce from it erroneous, particularly when referring to times of such slow improvement as the middle ages.

Decline of naval enterprise.

Edgar. The "mighty" fleets maintained by Edgar afford no information on the subject of this article, excepting that the facts connected with that monarch's annual circumnavigation of his territories prove them to have consisted of row-galleys. They must however have formed comparatively a "mighty" fleet; for, from a grant of land made by Edgar to Worcester cathedral, we find that he assumed to himself the title of "Supreme Lord and Governor of the Ocean lying round about Britain." That they were but of slight construction, we may infer from the low state of the navy so shortly after the death of Edgar as the reign of Ethelred, who, in order to re-establish it, instituted a regular tax for providing and maintaining a navy. It was enacted, according to Selden, that whoever possessed "310 hides of land, was charged with the building of one ship or galley; and owners of more or less hides, or part of one hide, were rated proportionately;" the hide being, according to the best authorities, as much ground as a man could turn up with one plough in a year. But this tax appears to have been inadequate to the purpose of providing a sufficient fleet, for all the exertions of Ethelred could not preserve Britain from again being ravaged by the Danes; and we find, that after the short reign of his son Edmund Ironsides, England was ruled by Danish monarchs. From the known talent of Canute, the first of these princes, and from the crowns of Denmark, Norway, and Britain being united in his person, we may presume that the naval affairs of England were not suffered to retrograde. We have indeed a record of their advance during this second Danish rule. We may also infer it from the present which was made by Earl Godwin to Hardicanute, the third Danish sovereign, of a galley, sumptuously gilt, and rowed by fourscore men, each of whom wore on his arm a bracelet of gold weighing sixteen ounces; not that the mere gorgeousness of the gift would prove any advance in the art of ship-building, but we may suppose, from its nature, that naval affairs found favour in the sight of this monarch. Of this we have also other historical evidence, as Hardicanute raised eleven thousand and forty-eight pounds, in the first two years of his reign, for the purpose of building thirty-two ships; and the taxes he levied for the support of his navy were so grievous that, Florentius says, scarcely any man was able to pay them.

Ethelred.

Canute.

Norman conques The marine of England seems to have been maintained on a comparatively powerful footing up to the period of the Norman conquest; and from the naval resources at the command of Harold the Saxon, in comparison with the insignificance of the shipping which brought William and his

Normans across the channel, there can be no doubt that had Harold relied upon his naval strength, the conquest of England would never have been achieved. But, by some fatality, his fleet, which had been long stationed off the Isle of Wight, was dispersed, in consequence of a report that William had abandoned his enterprise.

et of liam.

The flotilla of William the Conqueror is variously stated; by some at 900, by others at 3000 vessels. In either number we have a scale to estimate their insignificance, as the invading force consisted of about 60,000 troops, which would give in the one case about sixty-six men to each vessel, in the other twenty men only. Plate CCCCXLV. figs. 1 and 2.

The conquest of England being completed, the shores on either side of the narrow seas between England and Normandy were under the same rule. William therefore claimed sovereignty over them, which right was maintained by his successors. There can be no doubt that the constant intercourse between the two portions of the empire, which continued throughout the Norman sway, and indeed for a period of upwards of three centuries, must have done much towards fostering a maritime spirit among the population of England, and accustoming it to consider that fame and fortune were the rewards of nautical adventure.

obable e of ps.

We have but slight evidence as to the state of naval architecture during the early period subsequent to the conquest. There are a few facts scattered among the records of these times, which may enable us to draw some vague conclusions as to the probable size and nature of the vessels used. When Prince William, son to Henry I., was drowned, by the loss of the vessel in which he was crossing from France to England, it is recorded that three hundred souls perished with him. As of this number a large portion, historians say one hundred and forty, were men of rank, and as there were many ladies, since the prince was accompanied by his sister, the vessel must have been of considerable burthen. A similar event, namely, a shipwreck, that occurred during the reign of Henry II., by which nearly the same number of persons perished, tends to prove that such was about the extent of the accommodation afforded by the shipping of this period. Galleys still continued to be used for the purposes of war; but as commerce began to be extended, it became necessary to recur to the use of sails, and we find that they were therefore gradually recovering their importance, and superseding oars. Indeed it is difficult to conceive commerce to be profitably engaged in, attended with the immense expense of the crews necessary to propel the larger galleys. We should imagine that this had an important influence in the improvement of navigation and of naval architecture, for the commercial intercourse between the portions of the empire on either side of the channel must have been considerable. There is constant reference in the early chronicles to the great extent of the wine trade, and of the commerce in wool and woollen cloths.

te of de.

The introduction of vessels propelled by sails for the purposes of commerce would necessarily cause a change in the constitution of the fleets assembled for the services of war; and this we find to have been the case.

hard ur de on.

The expedition of Richard Cœur de Lion, in 1190, to join the crusade to the Holy Land, consisted of nine ships which are described as being of extraordinary size, 150 others of inferior dimensions, and only thirty-eight galleys. After the reduction of Cyprus, and the addition of the vessels captured there, with others which he had hired at Marseilles and in Sicily, his armament consisted of 254 "tall shippes, and about three score galliots." The increase was, therefore, almost wholly in the ships. This, together with the recorded fact, that he captured a Saracenic vessel of such size as to be capable of containing 1500 Saracens, and a large quantity of military stores, destined for the relief of Achon, tends to prove that the progress of naval architecture under the influence of the commercial powers of the Mediterranean, had been more rapid than in these northern seas, where the commerce was much more confined in its nature, and the nations bordering on which were in constant warfare with each other.

Sovereignty of the seas.

The Norman monarchs appear to have been very tenacious of their claim to the sovereignty of the narrow seas; and not only their claim, but their power to maintain their right, is admitted by the French historians. The Père Daniel sanctions the claim of Henry II. to this sovereignty.

John.

In the reign of John we find that the fleets of England were of such importance that the claim was extended; for it was then enacted, that if the masters of foreign ships should refuse to strike their colours, and thus pay homage to the English flag, such ships should be considered as lawful prizes. This monarch most carefully fostered the naval power of England; and it is in the records of the thirteenth year of this reign that we first read of any public naval establishment. There is in the close rolls published by the Record Commission, an order, which is dated the 29th of May 1212, from the king to the sheriff of the county of Southampton, in which he is directed without delay to cause the king's docks at Portsmouth to be enclosed by a good and strong wall, in order to protect the king's galleys and ships; and also to build storehouses against this wall for the preservation of the fittings and equipment of the said vessels; all of which works are to be performed under the direction of William, archdeacon of Taunton, and the greatest diligence is to be used, in order that the whole may be completed during the summer.

Early origin of Portsmouth dockyard.

Edward I.

The naval power of England appears to have continued sufficient to maintain the sovereignty assumed by John. For the occurrence of predatory excursions by some Genoese during the reign of Edward I. caused all the nations of Europe, bordering on the sea, to appeal to the kings of England, whom they acknowledged to be in peaceable possession of the "Sovereign Lordship and Dominion of the Seas of England, and Islands of the same;" which proves that their claim was generally acknowledged. This document, Evelyn says, was still extant in his time, in the archives of the Tower. The right to the absolute sovereignty of the seas was maintained up to the reign of James I. Queen Elizabeth insisted on and maintained her power to refuse or grant passage through the narrow seas, according to her pleasure. In 1634 Charles I. asserted his right to their sovereignty; and in 1654 the Dutch were compelled, after a severe struggle, to submit to it, and consent to "strike their flags and lower their top-sails on meeting any ship of the English navy in the British seas;" which homage the commanders of English men-of-war were instructed to exact from all foreign vessels until so lately as the close of the last war, when it was judiciously abandoned, for reasons which we shall give in the words of Sir John Barrow. In his Life of Howe, with reference to Trafalgar, he says, "That battle, moreover, having so completely humbled the naval powers of France and Spain, suggested to the consideration of the Board of Admiralty, with the approbation of the government, the omission of that arbitrary and offensive article which required naval officers to demand the striking of the flag and lowering of the top-sail from every foreign ship they might fall in with. That invidious assumption of a right, though submitted to generally by foreigners for some centuries, could not probably have been maintained much longer, except at the cannon's mouth; and it was considered, therefore, that the proper time had come when it might both morally and politically be spontaneously abandoned."

Error respecting the use of sailing vessels.

It is generally supposed, that ships intended only for sailing were first built by the Genoese, and that not until the beginning of the fourteenth century. We rather incline to the opinion, that in the Mediterranean they date from an earlier period than this; and that although the general adoption of the galley in Western Europe had much checked the art of navigation by means of sails, it had never been wholly lost, but that sailing vessels, though probably very few in number, and imperfect in their rig, had been constantly in use. If we may judge from the few hints handed down to us by history, they were probably luggers, and were adopted for mercantile purposes along the coast of the Channel and the Bay of Biscay. In the north of Europe sails had never been discontinued, although the more warlike galleys of England and France had gradually prevented the incursions of the northern nations into these more southern seas. The beginning of the fourteenth century is, however, decidedly an epoch in the histories both of navigation and of naval architecture, and from it may be dated the progress of navigation by means of sails. It is generally supposed, that the "large ships" mentioned in the enumeration of the fleets of this period, were ships built only for sailing, and intended for those long voyages which the invention of the compass by Flavio Gioia, a Neapolitan, about the year 1300, had rendered of comparatively easy performance.

Mariner's compass.

Edward III.

It has been surmised that the compass was brought to Europe from the East about forty years previous to this date, by Paulus Venetus. It is certain that the Portuguese found the knowledge of the magnetic needle generally and long diffused among the eastern navies. Evelyn says that "it was, near eighty years after its discovery, unknown in Britain." This is not improbable, for there does not remain much record of maritime affairs in the interval between the reigns of John and Edward III. This monarch's reign was, after a most severe struggle with France for supremacy on the seas, the era of a series of naval triumphs, and both navigation and naval architecture made most decided advances.

Naval battle.

In an engagement which took place in 1340, the French force amounted to four hundred vessels, of which a hundred and twenty were "large ships," these being principally Genoese mercenaries. Edward III. commanded the English fleet in person, which consisted of but two hundred and sixty sail. The French are variously reported to have lost twenty and thirty thousand men, and two hundred vessels are said to have been captured. The loss to the English was only four thousand men. Two facts are elicited by the accounts of this engagement; one is, that there is no mention of galleys as forming any part of the fleets; the other is, that in the James of Dieppe, which was captured by the Earl of Huntingdon, four hundred persons were found slain; consequently the size of the vessel must have been very considerable.

Royal fleet.

Use of cannon.

In 1344 Edward summoned commissioners from all the ports, to meet in the metropolis, provided with the state of their "navies." The roll of this fleet is inserted in the first volume of Hakluyt, from a copy in the Cottonian Library. The total numbers were 710 ships, and 14,151 mariners; and there were thirty-eight foreign ships, with eight hundred and fifteen mariners. From this roll we learn that galleys had ceased to be used by England, either in her wars or in her commerce, as neither among the king's ships, nor among those furnished by merchants, is there any mention of them. This fleet was that engaged in the celebrated siege of Calais, and it was probably at this time that cannon were first employed by the English. Camden in his Remains says, "Certain it is, that King Edward III. used them at the siege of Calais in 1347."

Sizes of Edward's ships.

Although from the fact of there being a royal dock-yard at Portsmouth so early as the reign of John, it is probable that the kings of England were possessed of a navy almost from the conquest; yet this roll of Edward's fleet contains the first enumeration of ships belonging to the sovereign, and employed in the service of the state, which occurs in English history; and, consequently, it is from the reign of Edward III. that we must date the formation of a royal navy. The king's ships were twenty-five in number, and were manned by 419 mariners. It appears that the vessels belonging to the sovereign were inferior in force to many of those which were supplied by subjects; for the average number of the crews of the king's ships was seventeen men to each vessel, while the average of the fleet was rather above twenty. Of course these numbers only include the mariners employed in navigating the vessels, and not the soldiers to be afterwards embarked on board them. If we consider the simplicity of the rig of these ships, in comparison to the wilderness of canvass and cordage covering the tall masts of a modern merchantman, we have more reason to be astonished at the large number of hands employed, than at the smallness of the averages seventeen and twenty. There is good reason to suppose that the addition of the bowsprit to the rig of ships dates no farther back than late in the reign of Edward III., which is alone quite sufficient to prove the very imperfect state of the navigation at that period, and also to excite astonishment that, with such apparently inadequate means, so much was effected; for history would almost lead us to suppose, that for all the purposes of war and commerce, fleets as proudly or as industriously ploughed the main then as now, "with all appliances and means to boot." Plate CCCCXLV. fig. 3.

Richard I
First navigation act

In the year 1381, the fourth of the reign of Richard II., the first navigation act was passed in England, for the encouragement of the naval interest, and the augmentation of our maritime power, by discountenancing the employment of foreign shipping. It enacted, "that for increasing the shipping of England, of late much diminished, none of the king's subjects shall hereafter ship any kind of merchandize, either outward or homeward, but only in ships of the king's subjects, on forfeiture of ships and merchandize, in which ships also the greater part of the crews shall be of the king's subjects." This act was not however enforced, permission being given to hire foreign shipping when there were no English ships in readiness.

Royal shi
hired by
merchant

Henry I

Letter t
Henry V

We have said that the royal navy of England must date from the reign of Edward III. We have proof that it continued to be customary for the sovereign to possess ships; they were, however, used both for war and commerce. This practice, which does not at all militate against the existence of a royal navy, appears to have commenced when "large ships" were substituted for the galleys as vessels for war; and it long continued to be usual for merchants to hire shipping from the sovereign for commercial voyages. We learn from the proceedings of the privy council, which have been printed by the Record Commission, that in June of the year 1400, Henry IV. ordered his "new ship," together with such others as were in the port of London, to proceed against the enemy. There is also a letter in the Cottonian Library, which has been printed in Ellis's Collection of Letters, from John Alcetre to King Henry V. concerning a ship building for that monarch at Bayonne. The letter is of the date of 1419; and as it contains more minute details than might be expected to have descended to us from such an early period, we give the following extract. "At the makyng of this letter yt was in this estate, that ys, to wetyng xxxvj. strakys in hyth y bordyd, on the weche strakys hyth y layde xj. bemys; the mast beme ys yn leynthe xlvj. comyn fete, and the beme of the hameron afore ys in leynthe xxxix. fete, and the beme of the hameron by hynde is in leynthe xxxiij. fete; fro the onemost ende of the stemne in to the post by hynde ys in leynthe a hondryd iij$^{xx.}$ and vj. fete; and the stemne ys in hithe iiij$^{xx.}$ and xvj. fete; and the post xlviij. fete; and the kele ys in leynthe a hondryd and xij. fete; but he is y rotyt, and must be chaungyd."

We have also evidence of the existence of ships which belonged to the monarch, in contradistinction to ships which

ibel of
lish
cie."

belonged to the "commons," in the quaint rhymes of an anonymous author of the year 1433, which have been preserved by Hackluyt, termed "The Prologue of the processe of the Libel of English policie, exhorting all England to keepe the sea, and namely, the narrowe sea, shewing what profite commeth thereof, and also what worship and saluation to England, and to all Englishmen."

> And if I should conclude all by the king
> Henrie the Fift, what was his purposing,
> Whan at Hampton he made the great dromons,
> Which passed other great ships of all the commons;
> The Trinitie, the Grace de Dieu, the Holy Ghost,
> And other moe, which as nowe bee lost.
> What hope ye was the king's great intent
> Of thoo shippes, and what in minde hee meant:
> It was not ellis; but that hee cast to be
> Lorde round about environ of the sea.

The term dromond is the corruption of a Levantine term, dromones, imported probably by the crusaders. The dromones were long row-galleys, but the adopted term dromond was applied generally to all large ships.

enry's
t.

There is a list of Henry's vessels in the fourth year of his reign, preserved in the proceedings of the privy council. His navy then consisted of three "large ships" or "grands niefs," three "carracks," eight barges, and ten balingers. In 1417 it was augmented to three "large ships," eight "carracks," six other ships, one barge, and nine balingers.

rly ton-
ge.

Again, in a letter preserved among the Cottonian manuscripts, and printed in Ellis's collection, we find that the Spaniards offered Henry V. two carracks for sale, one of which is described as of a tonnage equal to 1400, and the other to 1000 butts. So energetical was Henry V. in all things relating to his navy, and the consequent increase in the number of the royal ships during his reign was so great, as to have led to the error that before his time the sovereigns of England were not possessed of vessels, but relied wholly upon the aid to be gathered from the different ports of England, or to be hired from foreigners. This is evidently incorrect.

glect of
navy.

On the death of Henry V. a different line of policy appears to have been adopted; for in May 1423 the king's ships were all sold at Southampton, under a restriction that no foreigner could be a purchaser of them. But it appears that a long period did not elapse before the depressed state of the naval resources of the kingdom, consequent on this injudicious measure, attracted the attention of parliament. The following interesting quotation from the preface of the fifth volume of the Proceedings of the Privy Council, printed by the Record Commission, refers to this event. "In 1443 the attention of parliament was directed to this important part of the national defence (the naval force), and a highly curious ordinance was made for the safeguard of the sea. From February to November eight ships with forestages, or, as they were sometimes called then, as now, forecastles, armed with 150 men each, were to be constantly at sea. Every large ship was to be attended by a barge of eighty men, and a balinger of forty men. There were also to be 'awaiting and attendant upon them' four 'spynes' or 'spinaces,' with twenty-five men each. The whole number of men in these twenty-four ships was 2240."

There is also in the same preface an account of the various kinds of ships which formed the navies of this period, a part of which we shall quote, and by the addition of some further information of the same nature, derived from Froissart, Monstrelet, and other sources, the reader will be enabled to form a tolerably correct opinion as to the state of naval architecture in England previous to and during the fifteenth century. Plate CCCCXLVI.

ips.

Ships. "The burthen of the largest ships at that period probably did not exceed 600 tons, though some of them were certainly very large" as, for instance, the vessel built at Bayonne for Henry V., already mentioned. "One which belonged to Hull was released from arrest" (she having been pressed into the king's service), "because she drew so much water that she could not approach within two miles of the coast of Guienne, where the Duke of Somerset's army intended to disembark;" and several notices occur of ships of 300 and 400 tons and upwards. Some had three and others only two masts, with short topmasts, and a "forestage" or "forecastle," consisting of a raised platform or stage, which obtained the name of castle from its containing soldiers, and probably from its having bulwarks. In this part of the ship it appears business was transacted; and in the reign of Edward III., if not afterwards, ships had sometimes one of these stages at each end, as ships "*ove chastiel devant et derere*" are then spoken of. (Plate CCCCXLVI. figs. 2, 3, 4, 5.) Lydgate, describing the fleet with which King Henry V. went to France after the battle of Agincourt, says,

> Fifteen hundred ships ready there be found,
> With rich sails and high topcastle.

This is a confusion of terms. The "topcastles" were not the forecastles, but were castellated enclosures at the mastheads, in which the pages to the officers were stationed during an engagement, in order to annoy the enemy with darts and other missiles; as is frequently mentioned in Froissart, and is represented in the illuminations to his work. Plate CCCCXLV. fig. 3.

Carracks.

Carracks "were vessels of considerable burthen, and were next in size to great ships, in which class they indeed were sometimes included. Their tonnage may be estimated by their being in some instances capable of carrying 1400 butts; and the sail of one afforded Chaucer a strange simile expressive of magnitude,

> And now hath Sathanas, saith he, a tayl
> Broder than of a carrike is the sayl.

Though occasionally armed and employed against the enemy, they were more generally used in foreign trade."

Charnock says that the first carrack which was built in England was built for a merchant, John Tavenier, of Hull, who was consequently honoured by Henry VI. with distinguished favour; and she was licensed in 1449 with particular privileges to trade through the Straits of Morocco. The king also ordered her to be called the Grace Dieu Carrack. The license states her to have been built "by the help of God and some of the king's subjects."

Barges.

Barges "were a smaller kind of vessel and of a different construction from ships, though, like them, they sometimes had forecastles. Those appointed to protect the seas in 1415 were of 100 tons burthen, and contained forty mariners, ten men-at-arms, and ten archers; whilst the ships employed on the same occasion were of 120 tons, and had forty-eight mariners, twenty-six men at arms, and twenty-six archers each. Four large barges and two balingers were capable of holding 120 men-at-arms and 480 archers and sailors."

Balingers.

Balingers "were still smaller than barges, had no forecastle, and sometimes contained about forty sailors, ten men-at-arms, and ten archers." Froissart makes frequent mention of "balniers," "balleniers," which he describes "as drawing little water, and being sent in advance to seek adventures, in the same manner as knights and squires, mounted on the fleetest horses, are ordered to scour in front of an enemy, to see if there be any ambuscades." Monstrelet speaks of one vessel that was employed by Louis XI. to abduct the Count de Charolais, by the two names ballenier and balayer. It is not improbable that the name is derived from the French word *baleine*, and that its origin was similar to that of our English name whaler. The whale-fishery in Biscay was of a very early date.

Galleys.

Galleys (Plate CCCCXLVI. fig. 1) "are frequently mentioned at a very early period; and in the 5th Rich. II. 1381, the Commons complained that no measures had been taken to resist the enemy, who had attacked the English at sea with their barges, galleys, and other vessels. In 1405 Henry IV. directed his council to apply to the king of Portugal to lend him his galleys to assist the English navy against the French."

In Sir Grenville Temple's Travels in Greece and Turkey, we find the following description of a Maltese galley, or, more correctly, galleas, made from an old model preserved there. "These galleys measured a hundred and sixty-nine feet one inch in length, and thirty-nine feet six inches in breadth. They had three masts with latine sails, and were propelled by forty-nine oars, each forty-four feet five inches long. Their armament consisted of one thirty-six pounder, two of twenty-four, and four of six, all on the forecastle, which in those days had in reality some appearance of a castle. On each side of the vessel, aft of the forecastle, were four six-pounders." The total crew, including galley-slaves, consisted of 549 persons.

Galleas.

The *Galleas* and the *Galleon* appear to have been successive improvements on the original galley, rendered necessary by the introduction of cannon into naval warfare. The artillery introduced on board the early galleys was placed either before or abaft the rowers, and to fire in the direction of the length. (Plate CCCCXLVII.) In the galleas, a description of vessel first used at the battle of Lepanto, guns were also placed between the rowers, to fire from the broadside. Evelyn describes the galleasses he saw at Venice (1645) as being "vessels to rowe of almost 150 foote long and thirty wide, not counting prow or poop, and contain twenty-eight banks of oares, each seven men, and to carry 1300 men, with three masts." In the galleon the oars ceased to be the principal means of propulsion, and if used at all, were only so as occasional aids. The galley and galleas had overhanging topsides for the accommodation of the oars. In the galleon, on the contrary, the topsides "tumbled home" to so extraordinary an extent, that the breadth at the water was twice that at the topside, a fashion which has continued, but in a much less degree, to the present time. Plate CCCCXLVIII.

Spynes or spynaces.

Spynes or *Spynaces*, "now called pinnaces, seem to have been large boats, capable of holding twenty-five men, and were probably used for swiftness. To these must be added crayers, hulks, gabarres or gabbars, a kind of flat-bottomed boat used in shallow rivers." The French still continue to apply the term "gabarre" to store-ships.

Playtes and smaller vessels.

"Playtes, cogships, whence perhaps cogs and coggles are derived; farecrofts, passagers, which were perhaps boats used between England and France; and cock-boats, a small boat which attended upon all kinds of ships. The whole of these vessels were employed in conveying goods or passengers, and most of them on rivers or in the coasting trade. The ships, carracks, barges, balingers, and galleys, were employed equally for commerce or for war. When sent against the enemy, soldiers were put on board of them; and it is most likely they were at all times partly manned by soldiers. In foreign voyages they usually sailed in convoys; and it was a very ancient custom for the masters and sailors to elect their own admiral."

Foists or foysts.

In Burchett's account of the unfortunate action in the Bay of Conquet in 1513, in which the Lord High Admiral, Sir Edward Howard, lost his life, four *foists* are mentioned as forming a part of the French force. They were probably vessels of a similar character with the galley, but smaller in size. About the beginning of the seventeenth century, "carracks," "galleons," and "tall shippes" appear to have become synonymous terms. Plate CCCCXLVIII.

Hulks.

The term hulk originally was applied in a different sense from that which is stated in the part of the foregoing remarks which we have quoted from the preface to the proceedings of the privy council. Frequent allusion is made to hulks in documents of the fifteenth and sixteenth centuries. In a letter from Sir Thomas Seymour to the privy council, dated the 13th of November 1544, when in command of the "shipes whyche was a poyntede to kepe the Narrow Sees," vindicating himself for putting back on account of a storm, there is the following passage, from which we might almost infer that hulk was a general name synonymous with ships. "Thre holkes that come after me colde nott gett syght thereof (the 'Eylle of Wyght),' tyll they warre in a bay on the est syde of the Eylle, of the whyche Mr Strowd, Bramston, and Battersebe of the garde, God rest their sowles, was in on of them, whyche holke brake all her ankeres and cabelles, and she brake all to peses on the shorr, and but 41 of 300 saved a lyve. The other two rode out the storme, whyche lasted all that nyght and the next day. My brother (Sir Hy Seymour) and John Roberds of the garde, tryde the sees all the furst nyght, and the next day cam into Dartemouth haven, wharre my brothers holke strake on a roke and brest all to peses; but God be praysede, all the men warre savede, savying thre; and a nother new holke that tryde the sees that nyght brake thre of her bemes, and with moche ado came into the Wyght."

Again, in a letter from Lord Viscount Lisle, Baron Malpas, the Lord High Admiral of England, to Henry VIII., we have an announcement, that "their is cum into the Downes 30 sayle of hulkses, whereof sum be tall shipes." And again, in a letter from the same to the Lord Chamberlain, Lord St John, he speaks of having detained "3 grate hulkes bound, as they say, for Lusshborne, the leste of y^{m} 500 tunnes." And again, from the same to the same, he speaks of his former letter and the "goodly hulkes," and says, "sithens that tyme I have stayed other too, which in beautye and well appoynting are beyond the others. That I have last stayed ys a shipe of 600 at the least, and hath 5 toppes, and she ys of the town of Dansick, and ladon in Flanders for Lusshbourne."

State of mercanti shipping. Willian Canynge

The importance of the mercantile shipping of England during the fifteenth century must have been considerable. About the middle of it flourished the celebrated William Canynge, a merchant of Bristol, who built the church of St Mary's, Redcliff, in that city, in which church he was buried in 1474. This man appears to have been much in advance of the rude times in which he lived. His mercantile transactions were on so extensive a scale, and carried on in vessels of such large size, that they must have had an important influence in improving the navies of the period. It is therefore not only as a fact of much historical interest, but as one which is intimately connected with and most probably materially affecting our subject, that we shall dwell on the information which has descended to us respecting him. He was a great patron of the arts, a friend and protector of genius, and eminent for his virtue and piety. From an inscription upon his tomb, a tradition has become current, that Edward IV. took 2470 tons of shipping from him, he having "forfeited the king's peace;" and for the obtaining of which again, it is stated that Edward accepted these ships instead of a fine of 3000 marks. The Itinerary of William of Worcester, preserved in the library of Bennett College, Cambridge, gives the names of Canynge's vessels, among which are the Mary and John of 900 tons, Mary Redcliff of 500 tons, and Mary Canynge of 400 tons. The same authority gives the names and tonnage of other large ships belonging to Bristol merchants, among which are the John, of 511 tons, and the Mary Grace, of 300 tons. If there be any truth in the tradition of the confiscation of the shipping, it is probable that the inscription on the tomb may refer to some act of Canynge's in favour of the house of Lancaster, as he appears to have enjoyed the favourable opinion of Henry VI. Another account, which, it is said, is authenticated by the original instrument in the Exchequer, states that this Canynge assisted Edward IV. with a loan, and received in return a license to have 2470 tons of shipping free

story.

of imposts. In Corry's History of Bristol it is said, "the commerce and manufactures of Bristol appear to have made considerable progress during the fifteenth century, about the middle of which flourished the celebrated Canynge. This extraordinary man employed 2853 tons of shipping and 800 mariners during eight years. Two recommendatory letters were written by Henry VI. in 1449, one to the master-general of Prussia, and the other to the magistrates of Dantzic, in which the king styles Canynge his beloved eminent merchant of Bristol."

bts as
ccuracy
stimat-
size of
s.

Some doubt must always remain as to the actual size of the shipping of this remote period, as we cannot ascertain the bulk that was then considered as equivalent to a ton. It is probable that the tonnage was estimated according to the number of butts of wine that a vessel could carry. For we find references to ships sometimes by tonnage, and sometimes by the "portage" of so many butts.

ry VII.

This, however, is only a question as to exactness of size. In whatever way measured, Canynge's ships must have been of very considerable dimensions. It is rather extraordinary, that at the unsettled period in question Bristol should have enjoyed such a state of commercial prosperity as the ownership of such shipping as that enumerated by William of Worcester necessarily involves. Bristol, for many centuries, was only second in mercantile importance to London; but the civil wars which distracted the kingdom during a great part of the fifteenth century must have much retarded the increase both of the military and the mercantile navy of England; and only when order was again re-established by the accession of Henry VII. to the throne in 1485, ought we to expect men's minds to revert from the internal excitement of party strife to external affairs.

In this interval, in which England was torn by the wars of the houses of York and Lancaster, naval science had made more rapid strides than in any previous period of similar duration. The compass was not only known, but was generally adopted. Navigators could take observations by the use of an instrument called the astrolabe, invented by the Portuguese. The Spaniards and Portuguese were sufficiently advanced in the art of navigation to sail on a wind, and their smaller vessels, at least, were adapted for this manœuvre. New maritime states had started into existence. The Netherlands, until then scarcely known, was under the Duke of Burgundy, the most formidable naval power in the north of Europe. "His navy," says Philip de Commines, "was so mighty and strong, that no man durst stir in those narrow seas for fear of it, making war upon the king of France's subjects, and threatening them everywhere; his navy being stronger than that of France and the Earl of Warwick joined together." Venice, in 1420, according to Denina in his Revolutions of Italy, supported 3000 merchant-ships, on board of which were 17,000 seamen. They employed 300 sail of superior force, manned by 8000 seamen; had forty-five carracks, with 11,000 men to navigate them; and her arsenals employed 16,000 carpenters. Portugal had pushed her discoveries round the Cape, and Spain had added America to the world.

dHope.

The progress of discovery by the Portuguese to the south and east, and by the Spaniards to the west, with the consequent rapid increase in the importance of these two powers, and the influence of their discoveries on the state of Europe, renders the fifteenth century probably the most important of modern history. In it was given the death-blow to the increase of the Saracenic power, and to that of the Mediterranean states. The Turk, the Venetian, and the Genoese, had hitherto been the monopolizers of the commerce of the east. The discovery of the passage round the Cape of Good Hope opened this trade to all nations. The commercial sceptre, and consequently the military sceptre, hitherto shared by the Turk, passed wholly from the infidel to the believer. The crescent sank before the cross.

History.

Its influence on naval architecture.

There can be no doubt, also, that the "*tormentas*" of the "*grão Cabo de boa Esperaça,*" were a means of great improvement in naval architecture; for we find, that in consequence of the representations of Bartholomew Diaz, John II. of Portugal ordered ships to be constructed for the especial purpose of contending with the stormy seas of the Cape of Good Hope. The ships were built to form the squadron of Vasco de Gama, and were of small tonnage, from the very proper idea that small vessels were more adapted to prosecute researches in unknown seas than those of a large size, and consequent increased draught of water.

Squadron of Vasco de Gama.

The squadron of Vasco de Gama consisted of three ships and a caravella. One of the ships was of the burthen of two hundred tons, another one hundred and twenty, and the third one hundred; the caravella was of fifty tons. The largest of the ships was a victualler; the smallest was intended to prosecute discovery up creeks and shallows; and the other was for a display of force. As it is evident that it was not increase of dimensions which was to be the object in designing new vessels, the direction of improvement must have been towards perfecting their forms, strengthening their frames, and adding to the efficiency of their *materiel.* Portugal by these means became the most advanced state of Europe, in knowledge of the art of ship-building; for we find that it was long supposed that the passage to India required ships such as the Portuguese alone could build. Spain, in her career of discovery, conquest, and colonization across the mighty waters of the Atlantic, as if to assimilate the means to the vastness of her achievements, rapidly acquired the art of constructing ships of very large dimensions; and as long as she possessed a marine, her ships maintained this superiority.

State of naval affairs in England.

We have a curious instance of the light in which naval enterprises were considered in England at this time, notwithstanding the earnest desire of the monarch to re-establish his navy, which had necessarily suffered from the long civil wars. There is a letter from Henry VII. to the pope, preserved in the Cottonian Library, excusing himself from sending succour against the Turk, from which the following is a quotation. "The Galees commying from Vennes to England be commonly vij. monethes sailying, and sometimes more;" and again, "it should be May or they should be ready to saill, and it shall be the last end of Septembr or the said shippes shuld passe the Streits of Marrok; and grete difficultie to fynde any Maryners hable to take the rule and governance of the said shippes sailying into so jeopardous and ferre parties."

Henri Grace Dieu.

There is a drawing (Plate CCCCXLIX.) extant in the Pepysian Library in Magdalen College, Cambridge, of the Henri Grace à Dieu, built by the order of Henry VII., which Charnock has engraved in his History of Marine Architecture, and argues as to the general authenticity of the representation. He says, "this vessel may be termed the parent of the British navy. This celebrated structure, the existence of which is recorded in many of the ancient chronicles, cost the king, by report, nearly 14,000 pounds."

Early origin of naval terms.

From this drawing may be traced the derivation of one or two names which have been preserved even to the present hour; as, for instance, the "yard-arm," no doubt from the ends of the yards being armed with an iron hook. The castellated work from which we have the term "forecastle" is earlier than this; and the buckler-ports are most probably derived from a yet earlier period, when the bucklers of the knights were ranged along the sides of the ship, as they are represented in the illustrations of Froissart, and of the early chroniclers, and even in the Bayeux Tapestry. Plate CCCCXLV.

"The masts were five in number, inclusive of the bowsprit, an usage which continued in the first-rates without alteration till nearly the end of the reign of King Charles I.; they were without division, in conformity with those which had been in unimproved use from the earliest ages. This

History.

inconvenience it was very soon found indispensably necessary to remedy, by the introduction of separate joints, or top-masts, which could be lowered in case of need."

The drawing shows two tiers of ports. The introduction of port-holes is said to be an improvement due to a French ship-builder of Brest, named Descharges, in the reign of Louis XII., and about the year 1500. If the drawing be authentic, the correctness of this appropriation of the merit of the introduction of port-holes may be questionable.

Again, if the drawing be a correct representation of the vessel, she would have been in danger of upsetting, excepting in calm weather, and when her course was with the wind. In fact, as yet the large ships of war of England were not at all adapted to sail on a wind, and were very ill provided with such sails as would enable them to do so; they had therefore nothing to fear from the result of a measure which could not be put into execution. The fleets of war of which we have hitherto written seldom ventured out of port excepting in the summer months, and then only when the wind was favourable to their intended course. But very shortly after the date of the building of the Henri Grace à Dieu, we shall find that great improvement took place, and that in the reign of Henry VIII. there is evidence to prove that sailing on a wind formed one of the qualities of the vessels composing his fleets. This fact appears to throw some doubt upon the correctness of the drawing, for it must have required ships widely different from any of which that would at all give an idea, to have performed the evolution of tacking or wearing; and as the Henri Grace à Dieu was in all probability the same ship that on the accession of Henry VIII. was called the Regent, she must have formed one in fleets which were capable of performing these manœuvres. It is true that she may have been altered to adapt her to these new requirements of an improved system of seamanship; and it must also be said, that she was burned in an action with the French fleet, which occurred as early as the fourth year of the reign of Henry VIII.

Henry VIII. Sailing on a wind.

Though it is out of the question that ships with the enormous top-hamper which, on the evidence of all the drawings extant, still continued to be the fashion, could have made much progress in sailing on a wind, the letters of the time extant corroborate the statement we have made; for they begin to contain references to this improvement in navigation. In a letter from Sir Edward Howard, "Lord Admiral," to King Henry VIII., upon the state of the fleet, A. D. 1513, preserved in the Cottonian Library, and published in Ellis's collection, we find the following passage: "Ye commanded me to send your grace word how every shipp dyd sail; and this same was the best tryall that cowd be, for we went both slakyng and by a bowlyn, and a cool acros and abouet in such wyse that few shippes lakkyd no water in over the lee wales." The Lord High Admiral Lisle, in one of his letters (1545), says the small vessels of his fleet could "lye best by a wynde;" and in 1567 we have conclusive proof that there were "fore and aft," indeed "cutter-rigged" vessels, on the British seas; as in a map of Ireland of that date, published in the state-papers, two such vessels are represented, for the purpose, apparently, of indicating regular packets from England to Ireland.

It has been very generally supposed, on the authority of Sir Walter Raleigh, that the "knowledge of the bowline" was a discovery in navigation made shortly before his time; but we think it is probable that there were, even from the time of the Northmen, craft so rigged as to be capable of sailing on a wind. Froissart mentions, in several instances, "a vessel called a Lin, which sails with all winds, and without danger;" and again, "a vessel called a Lin, which keeps nearer the wind than any other." Boats with a rig adapted for this manœuvre are also represented in engravings of a very early date. In the plates of Breydenbach's Voyage to Palestine, which was published in 1483, boats and small vessels are represented with lateen sails; and in Braun's *Civitates Orbis Terrarum*, published in 1572, sprit-sails are met with. It is quite certain, however, that sailing on a wind was by no means a general quality possessed by the ships of war, or to any extent even by the greater portion of the larger shipping, until about the reign of Henry VIII. We shall adduce one other instance, in the account of the loss of the Mari Rose, a ship of the "portage of 500 tons," not so much to corroborate the fact of sailing on a wind, as to show that the two innovations, the introduction of port-holes, and the "knowledge of the bowline," were, as we have just said, in advance of the qualities of the large ships of war of the time. Sir Walter Raleigh says that "in King Henry VIII.'s time, at Portsmouth, the Mari Rose, by a little sway of the ship in casting about, her ports being within sixteen inches of the water, was overset and lost."

Histor

Loss of
Mari R

The loss of this ship has been the means of giving us another interesting insight into the comparatively low state of nautical skill in England at this period, namely, the middle of the sixteenth century. In a letter among the state-papers published under the direction of the Record Commission, addressed by the Duke of Suffolk to Sir William Pagett, "chief secretary to the kinge's highnes," dated the 23d of July 1545, and containing a schedule of things necessary to be had for the raising of the Mari Rose, one item is "fifty Venyzian maryners and one Venyzian carpenter;" the next item is "sixty Englisshe maryners to attende upon them." It would also appear that the attempt was to be made under the direction of an Italian, as the conclusion of the schedule is, "Item, Symond, petrone and master in the Foyst, doth aggrie that all thyngs must be had for the purpose aforesaid." The attempts however all failed; the wreck of the Mari Rose remains to this day at Spithead, and so lately as August 1836, several of her brass cannon, of most exquisite workmanship, were recovered from the sea by the enterprise and ability of an Englishman of the name of Deane.

Minutiæ
ship-buil
ing at th
period.

We may obtain some idea of the detail of ship-building rather before this period, from an account of a vessel built by James IV. of Scotland, at the close of the fifteenth or the beginning of the sixteenth century. The extract is from Charnock, but he has not mentioned his authority. "The king of Scotland rigged a great ship, called the Great Michael, which was the largest and of superior strength to any that had sailed from England or France; for this ship was of so great stature, and took so much timber, that, except Falkland, she wasted all the woods in Fife which were oakwood, with all timber that was gotten out of Norway; for she was so strong, and of so great length and breadth, all the wrights of Scotland, yea, and many other strangers, were at her device by the king's command, who wrought very busily in her; but it was a year and a day ere she was completed. To wit, she was twelve score foot of length, and thirty-six foot within the sides; she was ten foot thick in the wall and boards, on every side so slack and so thick that no cannon could go through her. This great ship cumbred Scotland to get her to sea. From that time that she was afloat, and her masts and sails complete, with anchors offering thereto, she was counted to the king to be thirty thousand pounds expense, by her artillery, which was very great and costly to the king, by all the rest of her orders. To wit, she bare many cannon, six on every side, with three great bassils, two behind in her dock and one before, with three hundred shot of small artillery, that is to say, myand and batterd falcon, and quarter falcon, flings, pestilent serpentens, and double dogs, with hagtor and culvering, corsbows and handbows. She had three hundred mariners to sail her, she had six score of gunners to use her artillery, and had a thousand men of war, by her captains, shippers, and quarter-masters."

Several of the writers of this period mention the fact of a ory.

Swe- ip.

Swedish ship of extraordinary dimensions built in the middle of the sixteenth century, and which was burned in an action between the Swedes and Danes in 1564. Chapman has given an estimate of the dimensions of this vessel. She was called the Makalos (by Charnock, Megala). According to Chapman, she was 168 English feet in length and forty-three English feet in breadth, an immense vessel for that period. Her armament was 173 guns, sixty-seven only of which could be considered as cannon, the remainder being merely swivels.

ards.

We find that Henry VIII., deeply sensible of the necessity of a permanent and powerful naval force, established the navy-office, and also several dock-yards for building and repairing the ships of the royal navy. Among these were Woolwich, Deptford, and Chatham. He also greatly added to and improved the dock-yard at Portsmouth. He invited from foreign countries, particularly from Italy, the commercial cities of which were still in advance of the rest of Europe in the maritime arts, as many skilful foreigners as he could allure, either by the hope of gain, or by the honours and distinguished countenance he paid to them. The following extract is from a report made to James I. in the year 1618, and published in the Archæologia. It was made in answer to a commission issued by that monarch to the several master-builders. The date of the report is rather in advance of our history; but we insert it here because the information it contains is of the time on which we are writing; as, while it confirms the statement we have just made, it informs us on the force of the royal navy during the reigns of Edward and of Mary, the period at which we have now arrived.

ard VI.

The minority of Edward VI., and the civil and religious strife which distracted the kingdom during the reign of Mary, depressed the resources of the state, and evidently much checked the progress of its maritime strength. The report says, "In former times our kings have enlarged their dominions rather by land than sea forces, whereat even strangers have marvelled, considering the many advantages of a navy; but since the change of weapons and fight, Henry VIII., making use of Italian shipwrights, and encouraging his own people to build strong ships of war, to carry great ordnance, by that means established a puissant navy, which in the end of his reign consisted of seventy vessels, whereof thirty were ships of burthen, and contained in all 10,550 tons, and two galleys. The rest were small barks and row-barges, from eighty tons downwards to fifteen tons, which served in rivers and for landing of men. Edward VI., in the sixth year of his reign, had but fifty-three ships, containing in all 11,005 tons, with 7995 men, whereof only twenty-eight vessels were above eighty tons each. Queen Mary had but forty-six of all sorts."

ects of hips of period.

There is one peculiarity about the fleets of this time, which exemplifies the defects of their design in a very remarkable feature. It is, that the ships built for the royal navy appear only to have been adapted for the lodgment of the soldiers and mariners, with their implements of war, and the necessary stores for navigation. The provisions were carried in an attendant vessel, called a "victualler," of which there was one attached to each of the large ships of war in the fleet, or to several of the smaller size. The hold appears to have been principally occupied by the "cook-room," the inconvenience of which arrangement, though much complained of, was general when Sir Walter Raleigh, in his Discourse on the Royal Navy and Sea-Service, recommended that it should be removed to the forecastle; and even so lately as 1715, several men of war had "cook-rooms" in their holds. There is also no doubt that the enormous quantity of ballast which was rendered necessary by the immense top-hamper of these ships, and the space which it occupied from being shingle, left but little room for the stowage of any quantity of provisions. In the ships built for commerce, this defect does not appear to have existed, as in fleets composed of the king's and of private shipping, those ships only which belonged to the royal navy had these attendant victuallers. We also know that the cook-rooms in the merchant-shipping were under the forecastle; and they had less top-hamper, as less accommodation was required for officers.

History.

Epoch in naval architecture.

Although we may comment on the comparative inefficiency of the vessels, we cannot but perceive that we have entered that period in the history of naval architecture and of navigation, in which, though still in their infancy, these arts may be considered as perfect in all but the maturity to be acquired by the experience of years. The mariner's compass was known; the theory of taking observations was understood, and the practice of it in the course of being perfected; and therefore the longest voyages could be undertaken with comparative certainty and safety. Besides this, the ships, though still imperfect, were becoming gradually manageable machines, and had ceased to be the cumbrous masses of the preceding ages, which, with few exceptions, were capable of little more than of being driven before the wind.

Three epochs in the maritime history of England.

If we consider the contents of the foregoing pages, there will appear to be three epochs in the maritime history of England; the first commencing with the introduction of galleys by Alfred, and ending with the reign of Edward III., before whose time these galleys and vessels propelled by oars were the chief instruments of navigation; the second ending with the reign of Henry VII., during which period, though sailing vessels were used for the purposes both of war and commerce, they were comparatively at the mercy of the winds, and, speaking generally, could sail only when they blew both fairly and gently; the third epoch we have already noticed. And henceforward we find the sister arts of navigation and naval architecture, if not always making rapid progress towards their present improved state, at least with no existing impediment to their advance towards that comparative perfection.

Elizabeth. Action with Spanish Armada.

We have seen, from the extract of the report of the builders, the state of the navy during the reigns of Edward VI. and of Mary. We know, therefore, that when Elizabeth ascended the throne, the marine of England, both military and mercantile, was in a very depressed state. The successful enterprise of Drake, and the fear of the Spanish Armada, aroused the energies of the country, and the force collected to resist the invasion amounted to 197 vessels of various descriptions, of the aggregate burthen of nearly 30,000 tons; thirty-four of which, measuring together 12,600 tons, composed the royal navy. It is true, that by far the larger portion were of small force. One only, the Triumph, was of 1100 tons; another, the White Bear, was of 1000 tons; two were of 800 tons, three of 600, six of 500, and five of 400; sixty-six were under 100 tons; and fifteen were victuallers, of which the tonnage is not mentioned. There are also seven other vessels included in the 197, which have no tonnage assigned them; but they must have been of small size, the number of mariners on board the whole seven being only 474. We have very conclusive means of comparing the Spanish with the English ships, and also of judging how very little naval arrangements were then understood, from their imperfect state even on board a fleet which had occupied the whole attention of the Spanish authorities for a space of three years, exemplified in the following anecdote; Burchett, in his account of the action of the 23d of July 1588, says, "The great guns on both sides thundered with extraordinary fury, but the shot from the high-built Spanish ships flew over the heads of the English without doing any execution; one Mr Cock being the only Englishman who fell, while he was bravely fighting against the enemy in a small vessel of his own."

Three-decked ships.

The Spaniards appear to have been the first to introduce a third tier of guns, the earliest mention of a three-decker being the Philip, a Spanish ship engaged in the action

History.

off the Azores in 1591, with the Revenge, commanded by Sir Richard Greenvil. The following armament of the Philip is extracted from a most spirit-stirring account of this tremendous action, which was written by Sir Walter Raleigh, and has been preserved by Hackluyt. "The Philip carried three tire of ordnance on a side, and eleven pieces in euerie tire. She shot eight forth right out of her chase, besides those of her stern portes."

We do not appear to have followed the example set by the Spaniards; for, during the long reign of Elizabeth, the ships of the royal navy were not much, if at all, increased in their dimensions, which was probably owing to the triumphant successes of her fleets, though, as we have seen, they were composed of ships generally much smaller in size than those opposed to them. We find from the list of the royal navy at the time of her death, in 1603, given by Sir William Monson in his tracts, that of forty-two ships composing the navy, there were then only two ships of 1000 tons, three of 900, three of 800, two of 700, four of 600, four of 500, and there were eight under 100 tons burthen. Two of these ships, the Triumph and the White Bear, are rated in this list each at 100 tons less burthen than in the list of the fleet in the year 1588, which we have already noticed.

James I.
Report of commission.

Shortly after the accession of James to the throne, several commissions were appointed to inquire into the state of the navy. From that of the year 1618, a very voluminous report emanated, of which the following is an extract, that affords an example of the state of knowledge on naval architecture at that time. "The next consideration is the manner of building, which in shipps of warr is of greatest importance, because therein consists both their sayling and force. The shipps that can saile best can take or leave (as they say), and use all advantages the winds and seas does afford; and their mould, in the judgment of men of best skill, both dead and alive, should have the length treble to the breadth, and breadth in like proportion to the depth, but not to draw above sixteen foote water, because deeper shipps are seldom good saylers, and ever unsafe for our rivers, and for the shallow harbours, and all coasts of ours, or other seas. Besides, they must bee somewhat snugg built, without double gallarys, and too lofty upper workes, which overcharge many shipps, and make them coome faire, but not worke well at sea.

"And for the strengthening the shipps, wee subscribe to the manner of building approved by the late worthy prince, the lord admll., and the officers of the navy (as wee are informed), on those points.

"1. In makeing 3 orlopes, whereof the lowest being placed 2 foote under water, both strengtheneth the shipp, and though her sides bee shott through, keepeth it from bildgeing by shott, and giveth easier meanes to finde and stopp the leakes.

"2. In carrying their orlopes whole floored throughout from end to end, without fall or cutting off y^e wast, which only to make faire cabbins, hath decayed many shipps.

"3. In laying the second orlope at such convenient height that the portes may beare out the whole fire of ordinance in all seas and weathers.

"4. In placeing the cooke roomes in the forecastle, as otherr war shipps doe, because being in the midshipps, and in the hold, the smoake and heate soe search every corner and seame, that they make the okam spew out, and the shipps leaky, and soone decay; besides, the best roome for stowage of victualling is thereby soe taken up, that transporters must be hyred for every voyage of any time; and, which is worst, when all the weight must bee cast before and abaft, and the shipps are left empty and light in the midst, it makes them apt to sway in the back, as the Guardland and divers others have done."

This commission was followed by several others during this and the succeeding reign, and from their reports arose many regulations tending much to the improvement of the navy, although the expenses incurred were, ostensibly at least, in part the means of causing the subsequent revolution.

His

Merca
shippi
this pe

In the early part of the reign of James I. the mercantile navy of England was reduced to a very low state, most of the commerce being carried on in foreign bottoms. The incitement offered by the advantageous trade which the Dutch had long engaged in to India at length aroused the nation, and the formation of the East India Company, which was the act of James, was followed by the building of the largest ship that had yet been constructed for the purposes of commerce, at least in England. The king dined on board of her, and gave her the name of the Trade's Increase. She is reported to have been of the burthen of 1200 tons. The impetus once given, before the end of the reign of James an important mercantile navy was owned by British merchants.

creas

Ship-
wrigh
Compa

Another interesting fact connected with this reign is the founding of the Shipwrights' Company, in the year 1605, and which was incorporated by a charter granted to the "Master, Warden, and Commonality, of the Art or Mystery of Shipwrights," in May 1612. Mr Phineas Pett, of whom we shall presently speak, was the first master. The draughts for the ships of the royal navy were subsequently ordered to be submitted to this company for approval previously to being built from. They also had jurisdiction over all builders, whether of the royal navy or of merchant shipping.

Draug
of shi
royal

Royal
Prince.

In 1610 the Royal Prince was launched; she was the largest ship which at that time had been built in England, and was also a most decided improvement in naval architecture. The great projection of the prow, a remnant of the old galley, was for the first time discontinued, and the stern and quarters assimilated more to those of a modern ship than to any which had preceded her. She is thus described in Stow's Chronicles: "A most goodly ship for warre, the keel whereof was 114 feet in length, and the cross beam was 44 feet in length; she will carry 64 pieces of ordnance, and is of the burthen of 1400 tons. The great workmaster in building this ship was Master Phineas Pett, Gentleman, some time master of arts at Emanuel College, Cambridge."

Phinea
Pett.

The same gentleman, Mr Phineas Pett, continued the principal engineer of the navy during the reign of Charles. The family of the Petts were the great instruments in the improvement of the navy, and, if the term may be allowed, of modernizing it, by divesting the ships of much of the cumbrous top-hamper entailed on them from the castellated defences which had been necessary in, and which yet remained from, the hand-to-hand encounters of the middle ages; and it is probable that, but for the taste for gorgeous decoration which prevailed during the seventeenth century, this ingenious family would have been able to effect much more; as it was, they decidedly rendered England pre-eminently the school for naval architecture during the time they constructed its fleets. This family can be traced as principal engineers for the navy from about the middle of the fifteenth century to the end of the reign of William III.

The P

First f
gate.

Evelyn, in his Diary, relating a conversation, says, "Sir Anthony Deane mentioned what exceeding advantage we of this nation had by being the first who built frigates, the first of which ever built was that vessell which was afterwards called the Constant Warwick (built in 1646), and was the work of Pet of Chatham, for a trial of making a vessell that would sail swiftly. It was built with low decks, the guns lying near the water, and was so light and swift of sailing, that in a short time she had, ere the Dutch war was ended, taken as much money from privateers as would have laden her." The dimensions of this vessel are given in Pepys's Miscellanies as follows: Length of the keel eighty-five feet, breadth twenty-six feet five inches, depth thirteen feet two inches, and 315 tons burthen; her "highest number of guns" thirty-two, and of crew 140.

Peter

Peter Pett, who built the Constant Warwick, was the son of Phineas Pett. He caused the fact of his being the inventor of the frigate to be recorded on his tomb. He was also the builder of the Sovereign of the Seas, in 1637, which was the first three-decker built in England. Her length over all is stated to have been 232 feet, her length of keel 128 feet, her main breadth forty-eight feet, and her tonnage 1637. Heywood describes her in the following terms: "She hath three flush deckes and a forecastle, an halfe decke, a quarter decke, and a round-house. Her lower tyre hath thirty ports, which are to be furnished with demi-cannon and whole cannon throughout, being able to beare them. Her middle tyre hath also thirty ports for demi-culverin and whole culverin. Her third tyre hath twentie-sixe ports for other ordnance. Her forecastle hath twelve ports, and her halfe decke hath fourteene ports. She hath thirteene or foureteene ports more within board for murdering peeces, besides a great many loope-holes out of the cabins for musket shot. She carrieth, moreover, ten peeces of chase ordnance in her right forward, and ten right aff; that is, according to land service, in the front and the reare. She carrieth eleaven anchors, one of them weighing foure thousand foure hundred, &c.; and according to these are her cables, mastes, sayles, cordage, which, considered together, seeing Majesty is at this infinite charge, both for the honour of his nation, and the security of his kingdome, it should bee a spur and encouragement to all his faithful and loving subjects to bee liberall and willing contributaries towards the ship money." Plate CCCCXLIX.

Of this ship, Fuller, in his Worthies, says, "The Great Sovereign, built at Woolwich, a leiger ship for state, is the greatest ship our island ever saw; but great medals are made for some grand solemnity, while lesser coin are more current and passable in payment." She was afterwards cut down one deck, and remained in the service, with the character of the best man-of-war in the world, until the year 1696, when she was accidentally burnt at Chatham.

About this time, 1650, appeared the first work connected with naval improvement ever written in this country, and by no less celebrated an author than Sir Walter Raleigh. It is very probable that his two discourses, the one on the Invention of Shipping, the other Concerning the Royal Navy and Sea-Service, had great influence in creating the interest which was evidently taken about this period in the improvement of the navy. Sir Walter says, "Whosoever were the inventors, we find that every age had added somewhat to ships and to all things else. And in my owne time the shape of our English ships hath been greatly bettered. It is not long since the striking of the top-mast (a wonderfully great case to great ships both at sea and harbour) hath been devised. Together with the chaine-pumpe, which takes up twice as much water as the ordinary did, we have lately added the bonnett and the drabler. To the courses we have devised studding-sayles, top-gallant-sayles, sprit-sayles, topsayles. The weighing of anchors by the capstane is also new. We have fallen into consideration of the length of cables, and by it we resist the malice of the greatest winds that can blow; witnesse our small Milbroke men of Cornewall, that ride it out at anchor half seas over betweene England and Ireland all the winter quarter; and witnesse the Hollanders that were wont to ride before Dunkirke with the wind at north-west, making a lee-shore in all weathers; for true it is that the length of the cable is the life of the ship in all extremities; and the reason is, because it makes so many bendings and waves as the ship riding at that length is not able to stretch it, and nothing breaks that is not stretched. In extremity, we carry our ordnance better than we were wont, because our nether-overloops are raised commonly from the water, to wit, betweene the lower part of the port and the sea. We have also raised our second decks, and given more vent thereby to our ordnance, tying in our nether-overloope.

"We have added crosse pillars in our royall ships to strengthen them, which being fastened from the kelson to the beams of the second decke, keepe them from setling or from giving away in all distresses.

"We have given longer floares to our ships than in elder times, and better bearing under water, whereby they never fall into the sea after the head, and shake the whole body, nor sinck sterne, nor stoope upon a wind, by which the breaking loose of our ordnance, or the not use of them, with many other discommodities, are avoided. And to say the truth, a miserable shame and dishonour it were for our shipwrights, if they did not exceed all other in the setting up of our royall ships, the errors of other nations being farre more excusable than ours. For the kings of England have for many years been at the charge to build and furnish a navy of powerfull ships for their owne defence, and for the wars only; whereas the French, the Spainards, the Portugalls, and the Hollanders (till of late), have had no proper fleete belonging to their princes or states.

"Only the Venetians for a long time have maintained their arsenal of gallyes, and the kings of Denmark and Sweden have had good ships for these last fifty years. I say, that the forenamed kings, especially the Spainards and Portugalls, have ships of great bulke, but fitter for the merchant than the man of warre, for burthen then for battaile. ...Although we have not at this time 135 ships belonging to the subjects of 500 tuns each ship, as it is said we had in the 24th yeare of Queen Elizabeth, at which time also, upon a generall view and muster there were found in England, of all men fit to beare arms, eleaven hundred and seventy-two thousand; yet are our merchants' ships now farre more warlike and better appointed than they were, and the royal navy double as strong as then it was.... We have not therefore lesse force than we had, the fashion and furnishing of our ships considered; for there are in England at this time 400 saile of merchants fit for the wars, which the Spainards would call gallions; to which we may add 200 saile of crumsters or hoyes, of Newcastle, which each of them will bear six demi-culverins, and foure sakers, needing no other addition of building than a slight spar-decke fore and afte, as the seamen call it, which is a slight decke throughout. The 200 which may be chosen out of 400, by reason of their ready staying and turning, by reason of their windwardnesse, and by reason of their drawing of little water, and they are of extreame vantage neere the shoare, and in all bayes and rivers to turn in and out; these, I say, alone, well manned and well conducted, would trouble the greatest prince in Europe to encounter in our seas; for they stay and turn so readily, as, ordering them into small squadrons, three of them at once may give their broad-sides upon any one great ship, or upon any angle or side of an enemy's fleet. They shall be able to continue a perpetuall volley of demi-culverins without intermission, and either sink or slaughter the men, or utterly disorder any fleete of crosse sailes with which they encounter.

"I say, then, if a vanguard be ordained of these hoyes, who will easily recover the wind of any other ships, with a battaile of 400 other warlike ships, and a reare of thirty of his majestie's ships to sustaine, relieve, and countenance the rest (if God beat them not), I know not what strength can be gathered in all Europe to beat them. And if it be objected that the states can furnish a farre greater number, I answer, that his majestie's forty ships, added to 600 before named, are of incomparable greater force than all that Holland and Zeeland can furnish for wars."

Ships of royal navy inferior to merchant-ships.

In the foregoing extract, we have strong evidence that the ships of the royal navy were generally inferior to those employed by the merchant-service, in the essential qualifications of being weatherly. This is exactly the conclusion that might be arrived at from the consideration, that a private individual would dispense with all that superabundance of top-hamper which was entailed on the ships of the royal navy, by the accommodation required for the numerous officers and gentlemen generally embarked on board them, and also by the mania for gorgeous decorations. This mania is well exemplified by the fact, that of the Sovereign of the Seas it is stated, " she beareth five lanthornes, the biggest of which will hold ten persons to stand upright, and without shouldring one another."

Sir Walter Raleigh, in his Discourse on the Royal Navy and Sea-Service, adverts to the same subject. He says, " We find by experience, that the greatest ships are lesse serviceable, goe very deep to water, and of marvellous charge and fearfull cumber, our channells decaying every yeare. Besides, they are lesse nimble, lesse maineable, and very seldome imployed. *Grande navio, grande fatica*, saith the Spainard; a ship of 600 tons will carry as good ordnance as a ship of 1200 tons; and though the greater have double the number, the lesser will turne her broad sides twice before the greater can wend once; and so no advantage in that overplus of ordnance. And in the building of all ships, these six things are principally required. 1. First, that she be strong built; 2. Secondly, that she be swift; 3. Thirdly, that she be stout sided; 4. Fourthly, that she carry out her guns all weather; 5. Fifthly, that she hull and try well, which we call a good sea ship; 6. Sixthly, that she stay well when bourding and turning on a wind is required.

" 1. To make her strong, consisteth in the truth of the workeman and the care of the officers.

" 2. To make her sayle well, is to give a long run forward, and so afterward done by art and just proportion. For, as in laying out of her bows before, and quarters behind, she neither sinck into nor hang in the water, but lye cleare off and above it; and that the shipwrights be not deceived herein (as for the most part they have ever been), they must be sure that the ship sinck no deeper into the water than they promise, for otherwise the bow and quarter will utterly spoile her sayling.

" 3. That she be stout, the same is provided and performed by a long bearing floore, and by sharing off above water even from the lower edge of the ports.

" 4. To carry out her ordnance all weather, this long bearing floore, and sharing off from above the ports, is a chiefe cause, provided alwayes that your lowest tyre of ordnance must lye foure foot cleare above water when all loading is in, or else those your best pieces will be of small use at the same in any growne weather that makes the billoe to rise, for then you shall be enforced to take in all your lower ports, or else hazard the ship.

" 5. To make her a good sea ship, that is, to hull and trye well, there are two things specially to be observed; the one that she have a good draught of water, the other that she be not overcharged, which commonly the king's ships are, and therefore in them we are forced to lye at trye with our maine course and missen, which, with a deep keel and standing streake, she will performe.

" 6. The hindrance to stay well is the extreame length of a ship, especially if she be floaty and want sharpnesse of way forwards; and it is most true, that those over-long ships are fitter for our seas than for the ocean; but one hundred foot long, and five and thirty foot broad, is a good proportion for a great ship. It is a speciall observation, that all ships sharpe before, that want a long floore, will fall roughly into the sea, and take in water over head and ears.

" So will all narrow quartered ships sinck after the tayle. The high charging of ships is it that brings them all ill qualities, makes them extreame leeward, makes them sinck deep into the water, makes them labour, and makes them overset. Men may not expect the ease of many cabbins, and safety at once, in sea-service. Two decks and a half is sufficient to yield shelter and lodging for men and mariners, and no more charging at all higher, but only one low cabbin for the master. But our marriners will say, that a ship will beare more charging aloft for cabbins, and that is true, if none but ordinary marryners were to serve in them, who are able to endure, and are used to, the tumbling and rowling of ships from side to side when the sea is never so little growne; but men of better sort and better breeding would be glad to find more steadinesse and lesse tottering cadge work. And albeit, the marriners doe covet store of cabbins, yet indeed they are but sluttish dens, that bread sicknesse in peace, serving to cover stealths, and in fight are dangerous to teare men with their splinters."

In Fuller's Worthies, we have also a short summary of the comparative qualities of the ships of different nations in the middle of the seventeenth century. It is as follows: " First, for the Portugal, his carvils and caracts, whereof few now remain (the charges of maintaining them far exceeding the profit they bring in); they were the veriest drones on the sea, the rather because formerly their seeling was dam'd up with a certain kind of morter to dead the shot, a fashion now by them disused.

" The French, however dexterous in land-battles, are left-handed in sea-fights, whose best ships are of Dutch building. The Dutch build their ships so floaty and buoyant, they have little hold in the water in comparison to ours, which keep the better winde, and so outsail them.

" The Spanish pride hath infected their ships with loftiness, which makes them but the fairer markes to our shot. Besides, the winde hath so much power of them in bad weather, so that it drives them two leagues for one of ours to the leeward, which is very dangerous upon a lee shore.

" Indeed the Turkish frigots, especially some thirty-six of Algier, formed and built much nearer the English mode, and manned by renegadoes, many of them English, being already too nimble heel'd for the Dutch, may hereafter prove mischievous to us, if not seasonably prevented."

During the early part of the seventeenth century, the Dutch navy rapidly increased in importance. Their success in having wrested from the Portuguese a share of the commerce of the east, emboldened them, in the then depressed state of the Spanish marine, to make a similar attempt on the west, and endeavour to establish settlements in South America.

The wars with Spain, in which they were consequently engaged, had such an important effect in establishing their maritime power, that in 1650 their navy consisted of 120 vessels fitted for war, seventy of which had two tiers of guns; and their fleet was in all respects the most efficient in Europe.

Evelyn, in his tract on Navigation and Commerce, speaking of the fisheries, says, " Holland and Zeeland alone should, from a few despicable boats, be able to set forth above 20,000 vessels of all sorts, fit for the rude seas, of which more than 7000 are yearly employed upon this occasion. 'Tis evident that by this particular trade they are able to breed above 40,000 fishermen and 116,000 mariners, as the census (1639) has been accurately calculated."

The tremendous struggle in which they were enabled by these means to engage with us shortly after this period, in consequence of the injurious operation of the navigation act on their commerce, had a most influential effect on the improvement of our navy, which at the commencement of the contest was very unequal to that of the Dutch; and it is probable that this war was the means of enabling us to contend triumphantly against the immense and unexpected attempts of Louis XIV. to wrest the sceptre of the seas from our grasp.

The sovereigns of the house of Stuart, without exception, appear to have devoted much attention to the improvement of the navy. Charles I. may be almost said to have lost both crown and life in consequence of these efforts; nor would it be doing justice to Cromwell to omit mention

story.

of the energy with which he took advantage of the all but despotic power which he possessed to increase his naval force. For this purpose not only many ships were built during the protectorate, but numbers of merchant-vessels were bought for the service of the state.

les II. perso- atten- to build- and al af- s.

After the restoration, Charles II. paid great personal attention even to the minutiæ of his navy, as we find by the following curious extract from a letter of his to Prince Rupert, preserved in the state-papers, and also by continual references to his naval predilections in Evelyn's and Pepys's Memoirs and writings. The letter is dated 4th August 1673. It says, "I am very glad the Charles does so well; a gerdeling this winter when she comes in will make her the best ship in England; next summer, I believe, if you try the two sloops that were builte at Woolidge that have my invention in them, they will outsail any of the French sloops. Sir Samuel Mooreland has now another fancy about weighing anchors; and the resident of Venice has made a model also to the same purpose. We have not yet consulted them with Mr Tippet nor Mr Deane; but hope when they are well considered, we may find one out of them that will be good."

Antho- Deane.

In Pepys's Diary, 19th May 1666, we find the following notice relating to one of the gentlemen mentioned in the above letter: "Mr Deane and I did discourse about his ship the Rupert, which succeeds so well, as he has got great honor by it, and I some by recommending him. The king, duke, and every body, say it is the best ship that was ever built. And then he fell to explain to me his manner of casting the draught of water which a ship will draw beforehand, which is a secret the king and all admire in him; and he is the first that hath come to any certainty beforehand of foretelling the draught of water of a ship before she be launched." This gentleman appears therefore to have been the first who applied mathematical science to naval architecture in this country. Pepys also says, "another great step and improvement to our navy, put in practice by Sir Anthony Deane," was effected in the Warspight and Defiance, which were "to carry six months' provisions, and their guns to lie 4½ feet from the water." This was in 1665.

t ap- ation of hema- l calcu- on to al ar- ecture.

History.

Sir Robert Slingeby.

We have hitherto in our historical sketch several times adverted to the probability that the merchant-shipping of England were superior in their sea-going qualities to those composing the royal navy. In a "Discourse touching the Past and Present State of the Navy," by Sir Robert Slingeby, knight-baronet, and comptroller of the navy, dated 1669, we have the following interesting statement, which points to a reason why this superiority of the merchant-shipping may have existed. "But since these late distractions began at home" (the Commonwealth), "forraigne trade decayed, and merchants so discouraged from building, that there hath been scarce one good merchant-ship built these twenty years past; and of what were then in being, either by decayes or accident, there are very few or none remaining. The merchants have found their private conveniences in being convoyed att the publick charge; they take noe care of making defence for themselves if a warr should happen." Yet he says in the time of Charles I. "the merchants continued their trade during the wars with France and Spain, if there could but two or three consort together, not careing who they met," they being little inferior in strength or burthen to the ships of the royal navy. The Discourse expresses much regret at this decay in the importance of the mercantile shipping, and recommends that measures should be taken to check the evil.

Decay of mercantile navy.

Sir Richard Haddock.

First analysis of the royal navy.

About 1684 Sir Richard Haddock, comptroller of the navy, adopted the example already set by Mr, afterwards Sir Anthony Deane, and directed an inquiry to be made as to "the number of cube feet that are contained in the bodyes of several draughts to their main water-line, when all materialls are on board fitt for saileing." The result of this inquiry was a very voluminous statement of the weights which made up the whole displacement of the fourth, fifth, and sixth rate ships, including minute details of their masts, yards, armament, &c. accompanied by perfect drawings of each ship. The original document is now in the possession of the writer of this article, having successively belonged to Sir Jacob Ackworth, Sir Jacob Wheate, and Mr Edward Hunt. The following table contains the dimensions and displacements, &c. of each class.

Table of Dimensions, from a Manuscript dated 1684.

	A First Fourth-rate near the largest dimensions.	A Second Fourth-rate near the dimensions of the Adventure.	A Fifth-rate of the largest dimensions.	A First Sixth-rate.	A Second Sixth-rate.	A Sixth-rate of the largest dimensions.	A Sixth-rate of the old fashion.

James II.

James II., from having so long and so gloriously filled the office of Lord High Admiral while Duke of York, was perfectly aware of the requirements of the navy; and during his short reign he paid great attention to increasing its efficiency. He also especially directed inquiries into the question of the durability of timber for the construction of it, and carefully accumulated both materials and stores for its maintenance. It is not a little curious that it was probably the attention which the monarchs of the line of Stuart had bestowed on the naval service, which enabled it so triumphantly to resist the persevering attempts of Louis XIV. to recover for them the throne of their ancestors.

The Revolution.

Though England was at the Revolution possessed of an efficient fleet, manned by experienced seamen, who had all the confidence arising from a series of naval triumphs, it must be remembered that for a long period no opposition to her naval superiority had been anticipated from any other power than Holland; and consequently the fleets of England were composed of ships which had many of them been built to adapt them to this service, for which small dimensions and light draughts of water were essential qualifications, on account of the shoalness of the Dutch coast.

William III.

William was too cautious a monarch to have neglected so important a means of national defence, as was the navy when engaged with such an ambitious and energetic opponent as Louis XIV.; and we find that the naval force was considerably increased, both numerically and in dimensions, during his reign. But the triumphs of our armies under Marlborough having for a time diverted the attention of the nation from naval affairs, it fell into decay during the reign of his successor.

Louis XIV.

When Louis XIV. determined to dispute with England for the sovereignty of the seas, he was not only without a navy, but without the means of forming one. The military and commercial marine of France had ceased to exist.

Rise of French naval power.

The sanguine temperament of the monarch, and the wisdom of his minister Colbert, removed all obstacles; commerce began to flourish on the quays, merchant-vessels to crowd the ports; dock-yards, harbours, and shipping appeared simultaneously to start into existence; and the nation, which almost for centuries had been essentially military, felt constrained to turn its energies to commerce and to the sea. A navy which in 1661 consisted of some four or five small vessels, in little more than ten years bearded and baffled the combined fleets of Holland and of Spain, and asserted the sovereignty of the Mediterranean. In 1681 her fleets consisted of 115 line-of-battle ships, manned by 36,440 men, with 179 smaller ships, the crews of which amounted to 3037 men; and in 1690 a fleet of eighty-four vessels of war, out of which three were of a hundred guns and upwards, and ten others were above eighty-four guns, with twenty-two fire-ships, was cruizing in the British seas. It is true that these mighty armaments failed in fulfilling the ambitious designs of Louis. But the severity of the struggle, which at length ended in the annihilation of his hopes, and in our triumphant assertion of our naval superiority, must always serve as an example of the danger we may incur by too great confidence in that superiority.

Comparison between English and French ships.

We have the following comparison between the French and British ships of about this period, from an official contemporary paper, by a gentleman of the name of Gibson: "Our guns being for the most part shorter, are made to carry more shott than a French gunn of like weight, therefore the French guns reach further, and ours make a bigger hole. By this the French has the advantage to fight at a distance, and wee yard-arm to yard-arm. The like advantage wee have over them in shipping; although they are broader and carry a better saile, our sides are thicker, and better able to receive their shott; by this they are more subject to be sunk by gunn shott than wee."

Injudicious management of royal navy.

The paper also complains much of the injudicious management of our shipping, by which it says, "many a fast sayling shipp have come to loose that property, by being over-masted, over-rigged, over-gunned (as the Constant Warwick, from twenty-six gunns, and an incomparable sayler, to forty-six gunns and a slugg), over-manned (vide all the old shipps built in the parliament time now left), over-built (vide the Ruby and Assurance), and haveing great tafferills, gallarys, &c., to the making many formerly a stiff, now a tender-sided shipp, bringing thereby their head and tuck to lye too low in the water, and by it takeing away their former good property in steering, sayling, &c. The French by this defect of ours make warr with the sword (by sending no small shipps of warr to sea, but clean), and wee, by cruseing in fleetes, or single shipps foule, with bare threates."

Charnoc opinions and paral lels.

Charnock draws some curious parallels between the state of the two navies of France and England during the earlier half of the eighteenth century, which may be summed up in a few words. That when the French took an English ship, it was seldom admitted into their navy; or, if admitted, it was only at a much lower rating, as, for instance, the Pembroke, a sixty-four in our service, became a fifty-gun ship in theirs. That in cases when an English fleet was in chase of a French fleet, it was ships which were British built which fell into our possession; but that almost on every occasion the French ships could evade ours. That the losses sustained in the French navy by foundering at sea, or by wrecks, were principally those ships which had been taken from us. That, on the contrary, the favourite ships in our fleets were those which had been taken from the French, and the instances in which French ships in our service were ever recovered possession of by them were extremely rare; we as far excelling them in all that related to the manœuvres and management of ships as they did us in designing them.

In consequence of the little attention bestowed upon the navy during the land-triumphs of Marlborough, it was found absolutely necessary, at the commencement of the reign of George I. that vigorous measures should be taken to re-establish it. Much pains were bestowed during this and the succeeding reign of George II. to improve its efficiency. The dimensions and the armament of the ships composing it underwent frequent revisals, and many valuable accessory improvements were made. Still it was evident that the perfect seamanship of the officers, and the undaunted valour of their crews, were frequently rendered nugatory by the superior qualities of the ships of their opponents, and the nation reaped little more than empty honour from the contests in which she engaged; the heavy sailers of England being unable to prevent her colonies and her commerce from suffering severely from the attacks of the light squadrons of her enemies. The naval commanders of England were constant in their complaints of the comparative inferiority in speed, in stability, and in readiness of manœuvring, of the ships under their command.

Lord R ney.

In a letter from Sir George (afterwards Lord) Rodney, dated the 31st May 1780, to Mr Stephens, the secretary of the Admiralty, is a passage which proves in a remarkable degree the truth of the above statement. "Nothing could induce them (the French fleet), to risk a general action, though it was in their power daily. They made, at different times, motions which indicated a desire of engaging, but their resolution failed them when they drew near; and as they sailed far better than his majesty's fleet, they with ease could gain what distance they pleased to windward."

Cause inferior of Engl ships.

One great cause of the inferiority of our ships arose from the practice which prevailed during the first half of the eighteenth century, through a mistaken idea of economy, of "rebuilding" old ships, so that, in fact, the forms and dimensions of the previous century passed down in many

History.

instances nearly to the end of this; and, with little stretch of the imagination, we may suppose, that under a continuation of the same ill-judged system, we should have had the representations of the carracks and galleons of the reign of Elizabeth in the fleets of the present day!

The French system of improvement was followed by the Spaniards, and the capture of the Princessa in 1740, of seventy guns, 165 feet in length and forty-nine feet eight inches in breadth, when our ships of the same force then building were only 151 feet long and forty-three feet six inches broad, caused an appeal to be made by the Admiralty to Admiral Sir John Norris, the then "naval oracle" of England. The consequence of the inquiries was, that the several master-shipwrights were directed to send in proposals for the future established dimensions of the navy; and in 1745 the Admiralty issued a new establishment for the dimensions of the several ratings of ships. The following table, taken from Derrick's Memoirs of the Royal Navy, contains the various established alterations from the reign of Charles II. to this of 1745, which was the last. Since then there has been considerable improvement, but there have been no fixed tables as established dimensions, at least none involving all the ratings.

The ships built after the establishment of 1745 are reported to have been stiff, and to have carried their guns well, but were still inferior to those of the French; and, consequently, about ten years afterwards an alteration was made in the draughts for the several ratings, and the dimensions were also slightly increased. It may not be uninteresting to remark, that the proportional breadths in the establishment of 1745 considerably exceeded those of more modern ships. Their breadth varied from $\frac{100}{349}$ to $\frac{100}{355}$ of their lengths; while, at the present time, with the exception of those built after the designs of the present surveyor of the navy, the breadths of most of our line-of-battle ships are within the limits of $\frac{100}{361}$ and $\frac{100}{383}$ of their lengths. We merely state this as a historical fact, not as advocating an undue increase of breadth. The question of the relative proportions of the dimensions of ships belongs to another portion of this article.

An Account showing the Dimensions established, or proposed to be established, at different times, for Building of Ships. Extracted from Derrick's Memoirs of the Royal Navy.

The Royal George was the first ship built on the increased dimensions, which were the result of the before-mentioned inquiry. She was laid down in 1746, and launched in 1756; and rather more than ten years afterwards, that is, in 1758, Triumph and Valiant.

the Triumph and Valiant of seventy-four guns were built on the lines of the Invincible, a French seventy-four-gun ship, captured in 1747.

We give the dimensions of these ships, as they were manifestations of an improved system, which, however, was not persevered in; for, with the exception of occasionally building after a French or Spanish model, the English ships were scarcely altered from those built at the commencement of the century.

Grand distinction between English and foreign navies.

There was still a very essential distinction between the navy of England and that of either France or Spain, which was this; that until after 1763 neither of these nations had any three-deckers in their fleets. Their largest armament appears to have been eighty-four guns on two decks, while we had third-rates which were three-deckers, as the Cambridge and Princess Amelia, launched in 1754 and 1757, and carrying only eighty-four guns. The capture of the Foudroyant, a French eighty-four on two decks, in 1758, caused a change in this respect, by furnishing the English with a model for a very superior class of men-of-war, which was adopted. Derrick, in his Memoirs of the Royal Navy, says, that "no eighty-gun ship with three decks was built after the year 1757, no seventy-gun ship after 1766, nor any sixty-gun ship after 1759."

French-built thr deckers.

During the peace that preceded the war with America, which commenced in the year 1768, the French had introduced three-deckers into their fleets, having found their eighty-fours on two decks to be no match for the more powerful of our three-deckers. Their first-rates were at this time generally of a hundred and ten guns on three decks. The Bretagne, one of these ships, was, according to Charnock, a hundred and ninety-six feet three inches long on the water line; and her moulded breadth was fifty-three feet four inches. Her displacement, it is stated in Sewell's Collection of Papers on Naval Architecture, was 4640 English tons. This can hardly be correct.

Establis ment of French fleets.

In 1786 the establishment of the French fleet was fixed by an ordinance, as according to the following table, which we extract from Charnock.

	Ships of 120 Guns.	Ships of 110 Guns.	Ships of 80 Guns.	Ships of 74 Guns.	Ships of 64 Guns.	Frigates carrying 18 Pounders.	Frigates carrying 12 Pounders.	Corvettes of 20 Guns.	Advice-boats, carrying four 4 Pounders.

George III. and George IV.

The ships of England continued throughout the wars of the reigns of George III. and George IV. notoriously inferior to those of France and Spain. The skill of our commanders, and the indomitable courage of our seamen, eventually succeeded in these, as in all former contests, in annihilating opposition, and in triumphantly asserting our naval supremacy. It cannot be denied that their task would have been comparatively easy, accompanied with less loss of life and expenditure of treasure, had their ships been more upon a par with those of their opponents.

Reasons for the continued inferiority of British shipping.

Although so much attention appears to have been directed at various times to the improvement of the navy, not only by the servants of the crown officially connected with it, but by the sovereigns themselves, we have seen that this continued inferiority of our ships to those of our opponents has been repeatedly asserted on undoubted testimony. The reason that all the attention thus bestowed failed in producing a corresponding beneficial effect was simply this; that in England the speculative ideas of men, undoubtedly of sense and judgment, as may be seen from the quotations of their opinions which we have made, but men uninformed as to principles, were taken as the rules for guidance. In France, on the contrary, the aid of science was called in, and some of the greatest mathematicians of the time turned their attention to the improvement of the shipping of that country; and it is a most astonishing fact, that the experience of more than a century of acknowledged inferiority to France, also with the admission that her superiority was caused by the researches of her mathematicians, should have still left it a question in England, whether our ships shall be designed on speculative opinions, or from scientific deductions. Colbert employed an engineer of the name of Rénau d'Elisagaray, a protégé of the Count de Vermandois, whose first essay was in the adaptation of ships to carry bombs, to be used in the then projected armament against the piratical states of the Mediterranean. Under the enlightened direction of Colbert, the French ships, which, by the ordinance of 1688, were much restricted in dimensions, were increased nearly one fourth in size, and every means taken which the then state of knowledge could suggest to insure a corresponding increase in good qualities. Rénau was, we believe, the first French author who wrote on the theory of ships. He was followed by the Bernoullis, by Père La Hoste, by Bouguer, Euler, Don Jorje Juan, Romme, and a host of others, the effects of whose writings we have traced in the progress of the improvements they introduced into the navies of France and Spain, and forced the navy of England to imitate. The only English treatise on ship-building that can lay any claim to a scientific character was published by Mungo Murray in 1754; and he, though his conduct was irreproachable, lived and died a working shipwright in Deptford dock-yard.

ance of rance.

A most palpable instance of the ignorance of all the principles of naval architecture among the authorities who were charged with designing our royal navy, even up to the close of the last century, may be quoted from an article in a recent periodical publication, the Papers on Naval Architecture, which was devoted to the advancement of this science, and which was for some years conducted by two gentlemen who were educated at the School of Naval Architecture at Portsmouth. The article in question was written by Mr Wilson of the late Navy Office, now Admiralty, a gentleman whose judgment, talents, and sound professional knowledge as a naval architect, contrasted with the humbleness of his situation, that of draughtsman to the surveyor of the navy, may also be cited as affording an instance of the mistaken policy of the successive naval administrations of England, as to the encouraging the application of science to naval architecture.

ee of Anson.

Mr Wilson, speaking of the cutting down of the Anson, a sixty-four-gun ship, to a frigate of thirty-eight guns, says, "she was cut down in the year 1794; and although in all other maritime states the science of naval construction was well understood, yet so culpably ignorant were the English constructors, that this operation, so well calculated, when properly conducted, to produce a good ship, was a complete failure. Seven feet of the upper part of the top-sides, together with a deck and guns, making about 160 tons, were removed, by which her stability was greatly increased; but, by a complete absurdity, the sails were reduced one sixth in area. In her first voyage the rolling was so excessive that she sprung several sets of top-masts. To mitigate this evil, in 1795 her masts and yards were increased to their original size; but as there was no decrease of ballast, she was still a very uneasy ship, and, as a necessary result, her wear and tear were excessive.

"Other sixty-fours were cut down, masted, and ballasted in exactly the same manner, and, it need scarcely be added, experienced similar misfortunes; and although they were improved by enlarging their masts and yards, they were still bad ships. Had their transformations been scientifically conducted, a class of frigates would have been continued in the navy, capable, from their size, of coping with the large American frigates; and thus the disasters we experienced in the late war, from the superior force of that nation, would, without doubt, have been not merely avoided, but turned into occurrences of a quite opposite character."

ety for Im- rement Naval hitec-

Several attempts have been made in England to alter this state of things, and to establish a system of scientific improvement in our ships. One was the formation of a Society, in 1791, for the Improvement of Naval Architecture, which numbered among its members the late sovereign, then Duke of Clarence, and many noblemen and gentlemen of rank, influence, and talent. This society arose out of the patriotic exertions of a bookseller of the name of Sewell, the proprietor of the European Magazine, who in an excursion to one of our seaports, heard such universal complaints as to the inferiority of the British ships compared with those to which they were opposed, that he devoted the covers of his magazine to correspondence on naval architecture, and gave a room in his house for discussion on the same subject, and for the reception of plans and models connected with it, which were always open to public inspection. The papers that were by these means collected were republished in two volumes; and, among much trash, there are several valuable articles contained in them. The society conducted a course of experiments on resistances of fluids, in the Greenland docks, on which they appear to have exhausted their resources and their energies, and that too without deducing any results which added to the previous knowledge on that subject. We are not aware that more than the first year's Report of their proceedings was ever published. Of this we have only met with one copy; and in consequence of the probability that the results of the society's experiments might be completely lost, they were republished in the Papers on Naval Architecture. They have been since republished in a most splendid form, and in a most patriotic spirit, solely for gratuitous distribution to scientific societies and individuals, by Mr Beaufoy, the son of the late Colonel Beaufoy, the gentleman to whom the task of conducting them was intrusted by the society, and on whom, it appears, a great portion of the expenses devolved.

Colonel Beaufoy.

School of Naval Architecture.

Another effort to improve the scientific knowledge of naval architecture in this kingdom was the establishment, in 1811, of a School for Naval Architecture in her majesty's dock-yard at Portsmouth. This was in consequence of the statements and recommendations contained in the Report of a Commission of Naval Revision appointed in 1806. These recommendations were founded on an inquiry into the education and attainments of the shipwright officers then in the dock-yards, "from their first entry as apprentices, to their elevation to the rank of surveyor of the navy." The Report stated as follows:—"In the whole course we have described, no opportunity will be found of acquiring even the common education given to men of their rank in life; and they rise to the complete direction of the construction of the ships on which the safety of the empire depends, without any care or provision having been taken, on the part of the public, that they should have any instruction in mathematics, mechanics, or in the science or theory of marine architecture."

Report of the Commission of Naval Revision.

The Report stated it to be among the most important parts of the duty of the Commission to endeavour "to put an end to that want of foresight and due consideration, which may finally lead to so much danger to the country; and to bring into our dock-yards apprentices of more liberal education than has hitherto been required."

The Commissioners recommended the establishment of two classes of apprentices. They proposed the arrangments necessary for putting their recommendations into practice, and also laid down a system of education for the first class. These proposals were directed to be carried into effect, by an order in Council of the 20th of September 1809, which was complied with in the establishment of the School of Naval Architecture on the first of January 1811.

School of Naval Architecture established.

The arrangements of the school were modified by a second order in Council on the 30th of January 1816, in consequence of a building for the reception of the students having been completed. By this order the establishment was incorporated with the Royal Naval College, and the number of students limited to twenty-four, that number being considered as "sufficient to supply the place of officers who may die or be removed," and therefore to fulfil the intentions of the Board of Naval Revision. This second order in Council stated, that the object of the institution was to introduce "a better and more skilful description of shipwright officers in his majesty's royal dock-yards;" and the "regulations established relative to the admission of students into the School of Naval Architecture," for the information of the candidates, stated that, "on the expiration of the apprenticeship, the students will be eligible to all situations in the ship-building department of his majesty's service; and in the event of there being no vacancy in any of his majesty's yards, they shall be employed as supernumeraries in the yards, until vacancies do occur," "provided the apprentice shall, at the expiration of the time above mentioned, have completed the plan of education, and shall be certified by the professor to be properly qualified."

History.

Number of students.

Forty-two gentlemen have been educated at this establishment, and twenty-two still remain in the ship-building department of her majesty's service, of whom many, bound to the service under heavy penalties, were, for eight or ten years after leaving the school, employed as supernumeraries in the dock-yards, awaiting their first appointments as foremen, although vacancies were during the interval continually occurring. Three only have been promoted to the step next above that of foreman; and, out of the last fourteen appointments to situations superior to that of foreman, only one has been conferred upon a member of the School of Naval Architecture.

The attempt has therefore most signally failed. For, from the comparative ages of the gentlemen of this establishment, and those of the officers who have been placed in these vacancies, there can be no rational hope that the expectations of the Commissioners of Naval Revision, or of the members of the Councils of State, can be fulfilled; and it may therefore now be said (in 1839), with as much truth as by the Report of the Board of Naval Revision in 1806, "nothing certainly can be more surprising than that, in a nation so enlightened as this is, and whose power, importance, and even safety, depend on its naval superiority, matters so essential to the preservation of that superiority should so long have been neglected."

Abolition of the school. Reasons of its failure.

The School of Naval Architecture was abolished in 1832; and we cannot write of the failure of this establishment without endeavouring to trace its causes, and to account for the strong prejudice which has existed against its members from the moment the first student's name was recorded on its books; a prejudice which has baffled them in every endeavour to obtain just attention to their claims from each successive naval administration, and which has virtually deprived the nation of the advantages anticipated by the Board of Naval Revision. That it is not in the failure of the students themselves to fulfil the conditions required of them, is evident, since the sole condition was that which we have quoted from the regulations, that they should complete the plan of education, "and be certified by the professor to be properly qualified." This the professor has officially complied with in the strongest terms. Nor is it that they are individually unfit to fill the situations which were guaranteed to them; for many of them are possessed of the most flattering testimonials of efficiency, as thorough practical officers, men of business, and gentlemen of principle. We believe it to arise solely from this, that the foundation of the establishment was accompanied by the most mortifying and humiliating reflections on the officers then filling the situations in the dock-yards, and, consequently, on all who rose to such situations from the working class of the yards. From these officers, to all of whom the very existence of the School of Naval Architecture has been a reproach, and a constant source of mortification, and to many of whom the advance of its members would operate as a bar to promotion, successive Admiralties have been contented to derive their information as to the success of that establishment, and the efficiency of its members. It surely would be expecting more than can be hoped from human nature in its most exalted state, to suppose such information could be given devoid of party feeling and of prejudice, or that men would voluntarily admit their own inefficiency, and concede to those whom they must regard as their rivals for the favours of the Admiralty; a merit equal, nay, on the very principle of the foundation of the establishment, superior, to that which they themselves possess. The First Lord of the Admiralty, therefore, for the time being, acting on information thus derived, annually asserts in his place in parliament, and believes his assertion to be correct, that these "young men" (men between forty and fifty years of age) "though gentlemen and men of education, yet want experience, and therefore cannot be promoted."

History.

It has bee productiv of much good.

The institution has however not been unattended with benefit to the service. The correct principles of naval architecture have become known and generally diffused; and though the members of the establishment may not reap the reward, the merit is undoubtedly theirs, for it has been through their instrumentality and from their works. It cannot, either, be denied that the officers of the dock-yards of the old school have had their energies aroused, and have risen in the scale of educated society, from their rivalry with the members of the new. On an inquiry into their competency to fill the situations in which they have been placed, though there would be many instances fully to warrant as great animadversion as was passed by the Board of Revision on their predecessors, there would also be found among them gentlemen, men of talent, and of considerable acquirements.

Sir William Symonds.

In 1830, Captain, now Sir William Symonds, was appointed to the office of surveyor of the navy, in consequence of having constructed a corvette, the Columbine, for her majesty's service, which was reported most favourably of after a trial cruize with other corvettes built from designs furnished by Sir Robert Seppings and the late Admiral Hayes.

The appointment of a naval officer to fill the solitary situation in the civil service of the navy which may be said to offer any great inducement to the exertions of the naval architect, was certainly of questionable policy. There are few clerks in the public offices of this country who do not early attain to salaries and retirements far exceeding those doled out to the highest offices in the engineering department of the navy, with this one exception; and to deprive the naval architect of this sole incitement to exertion, cannot but operate injuriously to the service, besides the evil resulting from having the head of a department, who must be presumed to be not only totally unacquainted with the detail of the duties of his subordinates, but also necessarily to be unqualified to perform a great portion of the duties connected with his own situation, and therefore to be dependent upon those from whom he is obliged to seek for guidance.

The office of surveyor of the navy, be it remembered, is an office of active operation rather than an office of supervision, and therefore essentially requires to be filled by a professional naval architect.

Sir William Symonds is the first constructor of the English navy who has been left unrestricted as to dimensions; and he has consequently been enabled to introduce into the service, ships which undoubtedly bear very high characters in some very decided points of efficiency as men of war. He has also practically demonstrated the possibility of ships of war obtaining sufficient stability without the aid of ballast, which is a very important advantage, and one which will yet be productive of essential benefit. But at the same time, being in error as to the true principles on which the stability of floating bodies is dependent, he has not obtained these advantages without, in many instances, incurring a compensating disadvantage, from uneasiness of motion, and which appears to be a very general complaint against the ships of his construction, some of them being most marked examples of the uneasiness attendant on a stability which depends almost wholly on breadth at the load-water section, to the neglect of the form of the solids of immersion and emersion.

His writings.

The opinions on which Sir William Symonds founds his system of construction have been explained by him, first in a brochure, printed, we believe, for private distribution, and then in an article, communicated by himself, in the United Service Journal for July 1832. To that therefore we refer our readers for information as to the principles upon which the fleets of England are now constructed. The following tables contain the dimensions of the various classes of ships which Sir William Symonds has introduced into the British navy; also the dimensions according to which the ships of

History.

the French navy are now being built, and the dimensions of one or two other modern ships about which considerable interest has been excited. The dimensions of the vessels designed by Sir William Symonds are obtained from Edye's Scales of Displacements, and from a list which was published in the United Service Gazette, and which we have endeavoured to verify; we therefore believe them to be correct. The dimensions of the French ships were procured in the French dock-yards during the summer of 1837, and are certainly correct. The London and Castor are obtained from Edye's Scales of Displacements; the Sapphire and Orestes from Morgan and Creuze's Papers on Naval Architecture; and the other dimensions are from the best available authorities.

Description of the manner of performing the Calculations incidental to designing a Ship, with Investigations of some of the principal Elements of the Design.

The labours of the numerous men of science who have devoted either the whole or a portion of their attention to the various problems embraced in the theory of ships, have left but few of its abstract principles uninvestigated; most of the properties of a ship have been examined, and the laws on which they depend clearly defined, either by the aid of mathematical demonstration, or by experimental induction. There are however some questions, which, though solved in theory, still depend on the results of physical experiment for perfecting their practical application.

Elementary principles may be classed in two divisions.

The elements of naval construction, a term very generally applied to the theory of ships, may be classed in two divisions; those which are solely dependent on known laws of nature, and those of which the solution involves laws of nature which are yet imperfectly developed.

The first division embraces by far the greater part of those

Of one the principles are established.

Practice apparently contradicts this assertion.

principles on which the most essential properties of ships depend; and it may now be said that the principal difficulties of these are surmounted, and are familiar to the instructed naval architect. These are alone sufficient to insure the attainment of a certain and considerable degree of excellency in a ship, to give it a preponderance of any peculiar property, to discover the causes of any bad quality, and to obviate its tendency by an appropriate remedy. In fact, they are enough, quoting from an article in an American Review, to "direct and limit the variations that may safely be made in the models at present in use, and guide us in the draught of new ones, suited to those changes in the force and magnitude of the several rates of vessels, which are continually making in the strife between the nations of the civilized world." Should the science of naval architecture never make further progress than it is thus described as having attained, it is evident that it is so far perfect as to be available for, and capable of being made to keep pace with, the wants of mankind. It may be objected, that the American writer assumes too high a standard, and that, so far from changes in the rate and magnitude of ships being made with the certainty attributed, each deviation from the beaten track seems but an isolated, baseless, and aimless venture, instead of forming one step in the progress of improvement. But, in justice to naval architecture, it should be remembered that the American spoke of the existing knowledge, and of the application of that knowledge in France, and in countries where its importance is recognised and its principles are known and cultivated, not in England, where its very claim to the rank of a science has been derided.

Second division embraces elements dependent on undeveloped laws of nature.

Mr Russel's researches on resistances.

Such knowledge not indispensable to the naval architect.

Propor- tions of t body, th positions and rake masts, pr portion an shape of sails, ma be deter mined by induction.

Danger of erroneous deductions unless made wit aid of scientific knowledge

The elements which may be classed in the second division, as those of which the solution resolves itself into a dependence on laws of nature which are as yet imperfectly developed, consist almost entirely of such as are dependent, in a greater or less degree, on a knowledge of the nature and laws of elastic and non-elastic fluids. This is a subject which has hitherto baffled alike the researches of the mathematician and the experimentalist; but, from the analogy of discoveries in other sciences, we may safely assert, that even its difficulties must be eventually surmounted by the patience and labour of the inductive philosopher. We are possibly on the eve of an important era, in so far as the laws of the resistances of fluids are involved. The researches of Mr Russel will apparently do much towards unravelling their mysteries, perhaps more than has as yet resulted from the labour of all preceding ages. Not that the perfect solution of these problems is really of such vital importance to the progress of improvement in naval architecture as it is often asserted to be, and which the apparent intimate connection of that science with the knowledge of fluids and of their laws would appear to sanction. Of those elements of naval construction which seem wholly to depend on such knowledge, some are restricted by considerations which are adverse to its application; and although it may be a desideratum in the determination of certain of the elements, the difficulties which arise from the want of it only require to be fully known and understood, to be, if not absolutely theoretically removed, at least, from the collection of facts, from experiment, and from analogy, so far overcome as to leave nothing to be desired on the score of practical utility. The form of a ship's body need not necessarily remain imperfect because the curve of the solid of least resistance is unknown, since enough has resulted from the consideration of the nature of that solid to prove that, however it might probably be applicable to the navigation of smooth waters, the perfect solution of the problem of its form could only be generally desirable to the naval architect, as contributing to the theoretic perfection of the science, and would add but little to its practical utility in its application to vessels which must encounter the tremendous powers of the elements in the open seas. Experience has proved, that a ship constructed with the bow and of the form which are recognised as at least nearly approximating to the solid of least resistance, would be unable to withstand the violence of the shocks of the motion of pitching, and of the waves; or, could she do so, would necessarily lose, by the additional resistance resulting from increased immersion, every advantage which might otherwise be anticipated. Neither can the exact position of the greatest section be a question of theoretic niceties, when the great capacity and the adjustments of form necessary to the exigencies of modern warfare and the advanced state of navigation are considered, which not only require a ship to be effective in all the *matériel*, and for all the purposes of war, when first from the hands of the builder, but to be equally so after long periods have elapsed and extended seas have been navigated. On the other hand, the comparative fulness of the fore and after bodies, the positions, rakes, and proportions of the masts, the adjustment and the shape of the sails, the bracing of the yards, and many other questions intimately connected with the resistance of fluids, may, and will eventually, be correctly determined by comparison, experiment, and induction, guided by the knowledge of those principles of science which are involved in them; and, without such knowledge to enable us to test and to establish the correctness of the conclusions which may be drawn, both experiment and comparison must be as useless in this, as, under similar circumstances, they would prove to any other branch of art. It has been most wisely said, that there are more false facts in the world than false theories. The reason is evident; the correctness of a fact is totally dependent on the competency of the observer; and how very few, even among those whose minds have been trained to habits of thought, are competent to the task of discriminating fact from fallacy. If there be few among such men, how much fewer in proportion must that number be among men of nncultivated minds, who can be capable either of observing facts, or of forming correct conclusions from those which they may have casually observed; and to such, almost without exception, has been confided the task of establishing the facts, and drawing the conclusions, upon which to found the theory of ships. as far as the development of that theory has been attempted in England.

Error in doing this

How it has arisen.

A most unphilosophic mode of reasoning is very generally applied to the question of the application of the exact sciences to naval architecture; and because chance on some few occasions, inductions from a tedious experience of failures on others, but far more frequently the results of observations on ships built by men of science, may have produced good ships, the question is often hastily decided, and the conclusion assumed, that since ships possessing more than an average of good qualities have been produced without abstract scientific study, therefore the exact sciences cannot be available to the advancement of naval architecture; the fact being placed quite out of the consideration, that the results of observations on ships designed by men of science are really the results of science, and that if the observations were made by persons competent to the task, these results would be onward steps in the progress of improvement.

The aid of induction cannot yet be dispensed with;

The time certainly has not yet arrived when the naval architect can effect with precision and confidence the synthetical composition of a perfect ship; but we have already asserted that he may, by the application of principles already established, proceed in the full confidence of producing one with a preponderance of good qualities.

for the theory of ships is yet imperfect.

The mistake is in the assumption that the theory of ships is already perfected, instead of merely being capable of being perfected by a rigid analysis of facts which daily experience would elicit were the abstract sciences applied to the task of analysing, collating, and registering them. It should always be remembered, that generally in every science a ory.

perfect theory is the result of the perfection of the science, rather than that the perfection of the science results from the theory. To argue against this principle, would be to retrograde from the nineteenth to the sixteenth century, and to affirm that Bacon has lived in vain.

We shall, in as concise a manner as is consistent with clearness of explanation, detail the method of performing the calculations necessary to determine the essential elements of the design of a ship's body, in the course of preparing the original draught or drawing.

A dy at re on a flu dis- pla s its we t.

A body floating at rest, upon a fluid also at rest, displaces as much of the fluid as is equal to the weight of the body. The truth of this proposition will appear from the consideration that the equilibrium between the body and the fluid is maintained by precisely the same upward pressure as supported the fluid which the body has displaced; and as the same pressure must support the same weight when there is an equilibrium, the weight of the floating body must be equal to that of a quantity of fluid equal in bulk to that part of the body which is immersed. It follows that the weight of the water displaced by a ship floating on it at rest, is equal to the weight of the ship and all its contents.

Di ace- me syno- ny us wit he we t.

It is usual to call the weight of the quantity of water which a ship displaces when she is floating at rest, her displacement; or, in other words, according to the foregoing proposition, the term displacement applied to a ship is synonymous with her weight.

To tain the eight of a ip.

To obtain, therefore, the total weight of a ship, it is only necessary to ascertain the weight of the volume of water which she displaces when floating at rest. This is found by calculating the number of cubic feet contained in a homogeneous solid equal in bulk to that part of the body below the surface of the water, and then multiplying this number by the specific gravity of the water, that is, by the weight of one cubic foot: the result will be the weight of the water displaced, and consequently also that of the ship.

Firs uide to d en- sion

That a ship of war may be able to carry and to maintain effective, in ordinary circumstances of weather, a determined armament, or a merchant-ship a certain lading, it is evident that the weight of the ship, and all that she is destined to contain, must be in such proportion to her bulk that she shall not be so far immersed in the water as to render her armament inefficient under circumstances in which its efficiency may be required; or her lading oppressive to her, if lading be the purport of her construction. The bulk of a ship is in proportion to her length, her breadth, and her depth. This, when the naval architect has ascertained the displacement necessary for his ship to possess, is his first guide to proportion her dimensions, so as to insure that displacement without undue immersion.

Gre st tran rse secti

The next step is to determine the form and area of a transverse vertical section at the largest part of the ship's body, which generally extends from the middle of the length for some distance towards each extremity. This section is called the midship section, and on its area is principally dependent the direct resistance which the vessel will experience, while the stability or resistance to inclination, and the easiness or uneasiness of her motions, are greatly dependent on its form.

Grea t hori al secti

Having to a certain extent fixed upon the midship section, the next consideration is to determine the area and form of a horizontal section at the surface of the water. This section is called the load water-section, or sometimes the "plane of flotation." On this section also the stability of the ship, in proportion to her dimensions, is very greatly dependent, as will be seen when we more fully explain that quality.

Dept n water nd differ e of dra ht of wat Bow a quarte section

The depth in the water, and the shape of the vertical section through the longitudinal axis of the ship, should next be determined; and then transverse vertical sections of the body between the midship section and either extremity of the vessel, generally at those parts where the body is intended to alter materially from the form of its midship section to that of the more sudden curvature at the extremities. An important consideration is involved in the forms of these sections, considerably influencing the easiness of the ship's motions. At present it will be enough to mention them as the next progressive step in the design;

Displacement.

after which the constructor has data sufficient to determine whether the dimensions he has chosen will enable him to obtain adequate displacement for the services required of his vessel. If so, he may proceed to trace in intermediate sections, and thus gradually, letting his design keep pace with his calculations, complete his drawing by the aid of processes which will be fully explained in a subsequent portion of this article, and which we therefore shall wholly omit here, as the limits of our space will not admit of repetition. Also, we can hardly describe the method of proceeding with the drawing until the principles which ought to guide us in forming the design have been investigated.

Diagonal, bow, and buttock lines. Inclined water-lines.

As we are totally unacquainted with the course of the fluid along the bottom of a vessel, it is essential that the curves bounding diagonal sections, called diagonal lines, and the curves bounding vertical sections, called buttock and bow lines, should be attentively considered, and also the curves bounding the inclined water-sections, that they may be such as, by comparison with other and acknowledged fast ships, may be presumed to be conducive to velocity. It must constantly be remembered, that naval architecture is a science of comparisons and of analogies; and no pains must be spared in rendering them subservient, not only to the design in progress, but to the eventual perfection of the science.

Alteration of seat in water from consumption of stores.

An important consideration connected with the forming the design of a ship is involved in the gradual alteration of the vessel's seat in the water from the consumption of stores. It is not only essential that a ship should be possessed of stability combined with easiness of motion, be weatherly and quick in manœuvring when she is stored and completed for foreign service as a ship of war, or fully laden as a merchant-ship; but it is equally essential that she should be possessed of these qualities towards the expiration of her cruize, or on her return light from her voyage. Designs for ships to be as perfect as the present state of knowledge can make them, must be made with reference to several water-lines.

Merchant-ships more uncertain in qualities than ships of war,

We see, therefore, that there are difficulties opposed to the improvement of the forms of merchant-ships, which do not exist to the same extent in opposition to the improvement of the forms of ships of war.

because of greater variation of seat in water,

In the designing of ships of war, the nature of the service in which they will be employed is known, and the lading, in comparison with that of a merchant-ship, is a constant quantity: it is therefore only necessary to endeavour to obtain a maximum of good qualities in relation to these circumstances. But in a merchant-ship the lading is of such a variable nature, both as to quantity and species, that the ship is at different times under very different circumstances; yet she is subjected to the same trials. Thus an East Indiaman, on her outward voyage, is two feet more immersed than on her homeward; and the draught of water of a collier is reduced, at different times, four, five, or six feet, by which the stability is generally very much diminished; and even with the same draught of water the stability may vary very considerably, owing to the difference in the nature and disposition of the lading, and the consequent effect produced on the centre of gravity of the ship; and yet, under these different circumstances, the ships are exposed to the same winds and seas. It is evident that if, when at their proper draught of water and stowage, they are only equal to the trials to which they are subject, they must be very inadequate to the contest with such a deduction from their powers as this would produce; particularly if their design be not made with a due consideration of this circumstance.

Theory.

The loss of stability which results from the diminution of draught of water cannot be compensated by a proportionate arrangement of sail, without incurring other evil consequences. If the quantity of sail, which at all times is comparatively small in a merchant-ship, be lessened, the wind on the increased hull might so counterbalance its effect, that she would be utterly unable to beat off a lee shore, or make any way on a wind.

causing diminution of stability, and increased uneasiness.

A ship is not only subject to a loss in stability when lightened, but becomes laboursome, on account of top-hamper: her rolling motion is more violent as her diminished depth in the water decreases the resistance which is opposed to the inclination, and she also generally becomes more leewardly, owing to the difference made in the resultant of the resistance, the diminution of the lateral resistance, and of her power of carrying sail.

That these effects are to be dreaded, is proved by the enormous loss of lives and property in light merchantmen, and especially light colliers.

Thus, for a ship which is intended for the various purposes of commerce, to be at all equal to a ship destined only to sail with a constant lading, more art is required in the design. But though this is a difficulty which opposes itself, it is no bar to progressive improvement, which is evident, as we are now suffering under the effects of such improvement, made, under all the same obstacles, by foreign powers.

Sacrifice of burthen necessary,

That the forms of merchant-ships may at all be benefited by the application of that knowledge which is possessed of the principles of naval architecture to their construction, a sacrifice in part must be made of those qualities which have hitherto been considered too exclusively at the expense of others. These are great capacity under small dimensions, and few men to navigate them.

by increased dimensions in proportion to displacement.

To enable them to sail and work well, their resistance must be diminished and their stability improved by an increase of dimensions in comparison with the displacement, by which they would gain in velocity, easiness of motion, power to carry sail, and consequently safety. But this would require a proportionally greater quantity of sail, and of course a larger crew to manage it; yet as other nations possess better ships than ourselves, and have therefore subjected themselves to this inconvenience of larger crews, that must not be considered as an insurmountable obstacle.

As the body of a ship is not generally any regular figure, the rules which determine the contents of regular solids will give only approximations when applied to finding its content; but the error arising from the application of the best methods now used for calculating displacements is so small as to be utterly insignificant in practice.

Atwood's rules for areas of curvilinear spaces.

The rules most applicable, and at present most generally applied, to the measuring of curvilinear spaces, by naval architects, are those published by Atwood in the Philosophical Transactions of the Royal Society for 1798. "They are founded on Sir Isaac Newton's discovery of a theorem, by which, from having given any number of points situated in the same plane, he could ascertain the equation to the curve which would pass through them all; and by means of this equation was enabled to express the ordinate in the curve corresponding to an abscissa of any given length, as well as the area intercepted between any two of the ordinates."

In order to determine the area of any curvilinear space by these rules, parabolic curves are supposed to pass through the extremities of a certain number of equidistant ordinates, dependent on the order of the parabola; for a conic parabola three ordinates, for a parabola of the third order four ordinates, and so on. It is evident that the correctness of the approximation of the parabolic area to the area of the required curvilinear space, is dependent on the distance between the ordinates; as on that depends the nearer or the more remote coincidence of the parabolic curve with the curve bounding the area required. An almost mathematical accuracy is attained in naval architectural calculations by assuming the ordinates to be one foot apart, even in those portions of the curvilinear areas in which the alterations of the ordinates are the most rapid, as in the fore, after, and lower parts of the body. But spaces considerably longer than this will be found to give results of great correctness.

Theo

Two on in use.

Atwood gives eight theorems for measuring curvilinear spaces, two only of which are necessary for the purposes of the naval architect. The first of these is applicable when the number of equidistant ordinates is odd. It is founded on the assumption, that each portion of the curve which passes through the extremities of three successive ordinates is a part of a conic parabola, and that the first of the three ordinates of each succeeding portion is the last of the three ordinates of the preceding portion. It is not necessary in this article to prove the correctness of these rules; it is sufficient to describe their application to the subject of the article.

First ru Numbe ordinat odd.

The first rule is as follows: Measure the lengths of all the equidistant ordinates. Take the sum of the extreme ordinates, then take the sum of the second, fourth, sixth, or even ordinates, and multiply it by four; and then take the sum of the remaining odd ordinates, or the third, fifth, &c., and multiply it by two. To the sum of these two products add the sum of the extreme ordinates, and multiply this sum by one third of the common interval between the ordinates; the result will be the approximate area required.

Second rule. Nu ber of or nates exceeds by unity a m tiple of 3.

The second rule, which is frequently useful, is applicable when the number of ordinates is one greater than a multiple of three. It is founded on the assumption that each portion of the curve which passes through the extremities of four successive ordinates is a part of a cubic parabola, and that the first of the four ordinates of each succeeding portion of the curve is the last of the four ordinates of the preceding portion.

This rule is as follows: Measure the lengths of all the equidistant ordinates. Take the sum of the extreme ordinates, then take the sum of those remaining ordinates which are one greater than a multiple of three, as the fourth, seventh, tenth, &c., and multiply it by two; and then take the sum of all the remaining ordinates, and multiply it by three. To the sum of these two products add the sum of the extreme ordinates, and multiply this sum by three eighths of the common interval between the ordinates; the result will be the approximate area required.

Their application find the contents solids.

Now, if we suppose that we have a solid formed by the revolution of a curve, and that the cubical content of that solid is required, we may first, by the application of either of the before-mentioned rules for obtaining the areas of curvilinear spaces, find the areas of a series of parallel and equidistant sections of the solid. Then, if we consider these areas as expressing ordinates to the abscissa of a curve, we shall have a curvilinear plane surface, the area of which will express the cubical contents of the solid. For it is evident that every increment of the assumed curvilinear area has correctly represented the contemporary increment of the solid.

We have here, then, rules of easy application, by which the areas either of the transverse vertical or the horizontal sections of a ship's body may be calculated, and by which also, from a series of the areas of either these vertical or these horizontal sections, the cubical content of a homogeneous solid, of the same shape and bulk as the immersed portion of the ship's body, may be determined; which cubical content, multiplied by the specific gravity of water, will give the displacement of the ship.

It will be seen, as we proceed with our subject, that it is necessary to ascertain the position of the centre of gravity of the homogeneous solid of the immersed part of the ship, and also, that in proceeding with the work of designing the heory.

essary nd the re of ity of homogeneous l of the ersed y, and e load er and ship ions. position e load er-sec- ; e mid- sec- ;

form of a ship's body, it will be necessary, in order, in the earliest steps, to confine the position of this point to certain limits, to calculate the situations of the centres of gravity of the load water-section and of the midship section; that these points, which will necessarily have great influence on the position of the centre of gravity of the displacement, may be determined with reference to their influence on the position of that point. These calculations are effected by a further application of the rules of approximation already given.

Every transverse ordinate of the load-water section being bisected at its intersection with the vertical longitudinal section passing through the stem and stern-post, the centre of gravity of the load water-section will necessarily be in the line of these intersections; it becomes therefore necessary only to find its position in this line. For the same reason, that of the bisection of the ordinates, the centre of gravity of the midship section will be in the line of its intersection with the vertical longitudinal section, passing through the stem and stern-post; and it becomes therefore only necessary to determine its position in this vertical line. And again, the centre of gravity of displacement must be always in the same before-mentioned vertical longitudinal section, unless the vessel be inclined from the upright, which consideration does not enter into the present question; it becomes therefore necessary to find its position in this section. In respect to length, this will be found in the line of intersection of some one of the transverse vertical sections with this vertical longitudinal section; and in respect to depth, in the line of intersection of some one of the horizontal sections with this same vertical longitudinal section; and, consequently, the position of this centre of gravity of the displacement, or, as some writers call it, the "centre of buoyancy," will be in the point of intersection of the three planes.

e homeneous so.

eral expsion for es of ty.

In order to determine the positions of these several centres of gravity, we must make use of this proposition in mechanics. If perpendiculars be drawn from any number of bodies to a given plane, the sum of the products of each body, multiplied by its perpendicular distance from the plane, is equal to the product of the sum of all the bodies multiplied by the perpendicular distance of their common centre of gravity from the same plane; and also of its corollary, that if any of the bodies lie on the other side of the plane, their distances must be reckoned as being negative. In applying this theorem to find the centre of gravity of any curvilinear space, by the application of either of the before-mentioned rules of approximation, each ordinate must be multiplied by its perpendicular distance from some given line, usually in a section near one of the extremities of the vessel: these products are then used as ordinates, and the rule is applied, and the calculations made, in the same manner as for finding the area of a space, the result, however, being the moment of the space. The moment of the space on the opposite or negative side of the line that was assumed from which to measure the perpendicular distances of the ordinates, is calculated by the application of the same means if the area be large; if small, a more simple method will easily suggest itself, and the moment thus obtained is subtracted from the former moment; the remainder is the total moment of the space, estimated from the assumed line, and this, divided by the total area of the same space, will give the distance of its centre of gravity from the assumed line. In this manner the centres of gravity of the load water-section and of the midship section may be found.

lica- to curear s by ood's ;

to s ids.

The position of the centre of gravity of the displacement is found by the application of the same rule of approximation. In order to determine its vertical distance below the load water-section, a series of equidistant horizontal sections must be drawn; then the area of each successive horizontal section is multiplied by its perpendicular distance below the load water-section, and these products are used as ordinates in either of the rules. The result is the moment of the space between the load water-section and the lowest horizontal section; to this must be added the moment of that part of the body which is below the lowest horizontal section. This will be obtained by multiplying its solid content into the vertical depth of its centre of gravity below the load water-section; the sum of these two moments is the moment of the whole displacement, estimated from the load water-section; and this moment, divided by the total displacement, will give the vertical distance of its centre of gravity below that load water-section. The position longitudinally of the centre of gravity of the displacement is obtained in a similar manner, by calculating the moment of that part of the displacement which is situated before some one of the transverse vertical sections, and also the moment of that part of the displacement situated on the opposite or negative side of the same section; then subtracting the negative moment from the positive, the remainder, which is the moment of the whole displacement estimated from the assumed vertical section, divided by the total displacement, will give the distance of its centre of gravity from the assumed vertical section.

Means of shortening foregoing calculations.

Instead of multiplying each ordinate by its perpendicular distance from the given line or plane, it is more convenient to multiply the successive ordinates by 1, 2, 3, 4, &c., and the sum of these products by the common distance between the ordinates, which of course produces the same result. A little consideration, in the course of performing the foregoing calculations, will suggest methods by which some of the labour may be lightened; such as the arrangement of the results in tabular forms, and the connecting the calculations for determining the areas, contents, or moments of those portions of the curves or solids towards the extremities with the general calculations. The foregoing account of the method of making the above calculations is given merely as an outline. For some of the more minute details, see Inman's Notes to Chapman; and mature consideration of the principles on which the calculations are founded will suggest all that can be further required.

Recapitulation.

The constructor having completed the foregoing calculations, will have ascertained the area of the midship section, the area of the load water-section, the displacement, the positions of the centres of gravity of these two sections, and also the position of the centre of gravity of the displacement. The areas of the two sections, and the positions of their respective centres of gravity, were required to be determined, on account of the influence of these areas and these positions on the content of the displacement, and the position of its centre of gravity, and also in consequence of their influence on the stability of the ship. It must therefore be remembered, that if the results of these previous calculations do not accord with the intentions of the constructor, or are inadequate to the development of his design, he must make such alterations in his curves or in his dimensions as he may consider necessary, before proceeding further with his design. And if he shall have sufficiently informed himself on the theory of ships, he will be enabled to do so with considerable confidence at this stage of his progress, as to the final result of his work.

Conditions of equilibrium of a body floating on a fluid at rest,

We have before said that a body floating on a fluid is supported by the upward pressure of that fluid. This body will be in equilibrio when the direction of this upward pressure passes through the centre of gravity of the part of the body which is immersed in the fluid, and also through the centre of gravity of the body. These two centres will therefore be in the same vertical line, and this vertical line will be the line of intersection of the transverse vertical section in which the centres of gravity of the displacement and of the body are situated, with the longitudinal vertical section of the body. Consequently, when a ship is floating on the water in a state of rest, and only acted upon by the upward pressure of the water, the centres of gravity of the ship and of the displacement are in the vertical middle line of the same transverse vertical section.

When acted upon by an inclining force.

But when the ship is inclined by the action of some second force, as that of the wind, a part of the body which was previously immersed is emerged, and a part which was above the surface of the water is immersed; consequently the form of the portion of the body under the water is altered, and the centre of gravity of the displacement is carried over towards that side on which the increased immersion has taken place, while the position of the centre of gravity of the ship, with reference to its position in the ship, has remained unaltered, that being the point about which the revolution has taken place. But though the form of that part of the ship's body which is beneath the surface of the water after the inclination, will differ from the form of that which was beneath the surface before the inclination, the total displacement will continue the same, since the weight of the ship has not been either increased or diminished by the inclination; consequently the solid content, or the displacement of that portion of the body which is immersed by the inclination, will be exactly equal to the solid content, or the displacement of that portion which is emerged by the same cause.

Solids of emersion and immersion.

But the forms of these two solids, which we shall call the solids of immersion and emersion, are not necessarily similar, and therefore their centres of gravity are not necessarily situated in the same transverse vertical section of the vessel. If the centres of gravity of these two solids should be situated in the same transverse vertical section, the inclination of the ship will be round her longitudinal axis; but if the centre of gravity of the solid of immersion be situated either before or abaft the transverse vertical section in which the centre of gravity of the solid of emersion is situated, in either case the motion of the ship in performing the inclination cannot be round an axis coincident with its longitudinal axis; and the position of the centre of gravity of the displacement, in passing to leeward of the position which it occupied before the inclination took place, will be influenced by the relative situations of the centres of gravity of these solids of immersion and emersion.

Their effect on the centre of gravity of displacement.

As this irregularity of motion is injurious to the ship, it is desirable to obviate it by regulating the form of the body, both above and below the load water-section, in such a manner that the centres of gravity of the solids of immersion and emersion may be in the same transverse vertical section of the ship. The form of that part of the body situated above and below the load water-line is also dependent upon the following considerations. Although the total displacement after the inclination must necessarily be the same as that before the inclination, the shape of the ship's body may be such that there will be a tendency to immerse a greater or a less solid on the one side than is emerged on the other; which tendency will have the effect of causing the axis of rotation, and consequently the centre of gravity of the ship, to rise or fall in space during the inclination, and fall or rise in space during the return to the upright position; for since the total displacement of the ship continues constant, the solid which is actually immersed cannot exceed that which has emerged.

Their effect on the centre of gravity of the ship.

It is therefore evident that the existence and extent of this motion must depend upon the position of the centre of gravity of the ship, and also on the form of those parts subject to alternate immersion and emersion. For the better illustration of this point, we will suppose a ship of such a form, that when she is floating upright on the water, her sides between wind and water, that is, those parts of her sides subject to the alternate immersion and emersion, are vertical.

First case.

We will first assume that the centre of gravity of this ship is coincident with the centre of gravity of the load water-section. In this case there will evidently be no tendency in the ship either to rise or fall during the inclination, because the two prismatic solids intercepted between the load water-sections before and after the inclination are equal, and the axis of revolution of the ship is coincident with the line of intersection of the two load water-sections.

Second case.

Now, if we assume the centre of gravity of the ship to be situated beneath the load water-section, and the inclination to take place, this centre being the axis of inclination, there would be a much larger solid immersed than was emerged, because the line of intersection of the two load water-sections would be to windward of the longitudinal vertical section of the ship; but in order to restore the equilibrium between the upward pressure of the water and the weight of the ship, the axis of rotation or centre of gravity of the ship must rise until these two solids become equal.

Third case.

Again, in the case when the centre of gravity of the ship is situated above the load water-section, it will be evident that the tendency of the inclination of the ship round it would be to raise a larger solid out of the water than would be immersed on the other side, unless the weight of the ship, in its effort to restore the equilibrium between the upward pressure of the water and itself, were to cause the centre of gravity of the ship to be lowered until the two solids became equal.

General conclusions.

Now, if we suppose the sides of this same ship were formed in such a manner as to fall outwards from the load water-section upwards, we shall easily perceive, that in the case where the centre of gravity was supposed to be beneath the load water-section, the injurious quality would be increased; while in the case in which it was supposed that the centre of gravity was above the load water-section, it would be diminished. The foregoing examples are sufficient to illustrate the principle on which this cause of uneasiness of motion in a ship depends, and also to point out the means which must be taken to obviate it. We see, then, that it is essential, not only that the centres of gravity of the solids of immersion and emersion should be in the same transverse vertical section, but also that these solids should be as nearly equal to each other at all inclinations as possible, and that the greater the deviation from equality between the solids of immersion and emersion, the greater the strain the ship will be subjected to, and the greater will be the uneasiness of her motions.

Adjustment of these solids.

In order to obviate this fault, it would be necessary to compute the exact position of the centre of gravity of the ship when completely ready for sea, that the correct prismatic solids of immersion and emersion might be ascertained and adjusted to equality, and to have their centres of gravity in the same transverse vertical section.

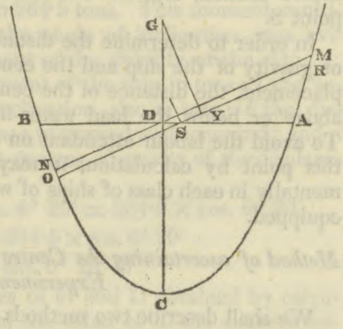
Labour attendant on determining centre of gravity of ship.

But the computation of the exact position of the centre of gravity of a ship completely fitted is a task of such magnitude, and, in consequence, of such hazard of incorrectness, that it can scarcely be considered practicable. Its position must be determined in relation to the three dimensions, length, breadth, and depth; relatively to two of these, however, it is ascertained from the consideration that it is necessarily in the same transverse vertical section as the centre of gravity of the displacement, and that, as it must also evidently be in the longitudinal vertical section of the ship, it must be in the line of intersection of this transverse vertical section with the longitudinal vertical section of the ship. But its position in relation to the load water-section, if not determined by experiment, must be ascertained by a most tedious and laborious calculation of the moments of the weights estimated from the load water-section, the sum-total of which moments being divided by the displacement of the ship, will give the perpendicular distance of the centre of gravity from the load water-section. This process has been gone through for several two-decked line-of-battle ships at the late School of Naval Architecture, and it was ascertained that the positions of their centres of gravity varied from seven to nine inches above the load water-section. We shall, in its proper place in this article, describe the manner of finding experimentally the position of the centre of gravity of a ship, merely here premising, it is assumed generally, that in ships of war the centre of gravity is rather above the load water-section.

In almost all classes of vessels, several of the transverse vertical sections on each side of the midship section are similar and equal to it, and generally the form of these sections is such, that there would be but little disturbance, during the inclination of the ship, in the adjustments of the solids of immersion and emersion; but the sections before and abaft these, as they approach the extremities, become more dissimilar in those portions of them above and below the load water-section; consequently, although, as has before been said, the total volumes of immersion and emersion must necessarily be equal, the areas of the sections of the immersed and emerged solids, at any given transverse vertical section of the body, need not be equal; it becomes therefore necessary to determine the position of the intersection of the inclined load water-section with the load water-section of the ship in her upright position.

T deter- m e line of in rsec- ti , of ho- ri ntal w in- ci ed load w er-sec- ti

Fig. 1.



Suppose G (fig. 1) to be the centre of gravity of the ship, AB the water-line when she is upright, and let it cut the vertical line GC in the point D. From the centre of gravity G draw GY, making the angle DGY equal to the supposed angle of inclination of the ship. Take GY equal to GD, and through the point Y draw the line OR perpendicular to GY. Then OR is the water-line which the ship will assume after the inclination. Let this inclined water-line intersect the water-line AB in the point S. Through D draw NM parallel to OR. It is clear that, supposing the centres of gravity of the solids of immersion and emersion to be in the same transverse section, in every vertical transverse section of the ship the distance DS will be the same, and the several points S, S, S, will be in the straight line forming the intersection of the two load water-sections, which line of intersection will be parallel to the longitudinal axis. Now, if, by a calculation of the contents of the solids of immersion and emersion, which are represented in the figure by the triangles ASR and BSO, which contents may be calculated by either of the rules for approximation, they are not found to be equal, they must be altered until they become so. In order to find the position of the point S, or the distance DS, we have the area ASR equal to the area BSO, which call equal to A, and let the area DSRM $= a$, and the area DSON $= b$,

$$\begin{aligned} \text{then ADM} &= A + a, \\ \text{BDN} &= A - b, \\ \text{and ADM} - \text{BDN} &= a + b = \text{MNOR} \\ &= \text{MN} \times \text{ST nearly}, \\ &= \text{MN} \times \text{DS} \times \text{sin. of inclin.} \end{aligned}$$

$$\text{or DS} = \frac{\text{ADM} - \text{BDN}}{\text{MN} \times \text{sin. of inclin.}}$$

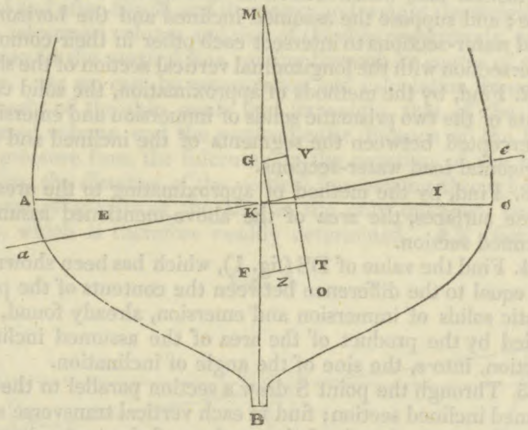
In order to obtain the areas of the sections of the prismatic solids, chords may be drawn in each, which will divide it into two others, a triangular and a parabolic area. The triangular area will be equal to half the product of the base multiplied into its perpendicular height. The parabolic area will be equal to two thirds the base multiplied into its perpendicular height. The moment of each of these areas may then be found by taking the sum of the product of the area of the triangle multiplied into the distance of its centre of gravity, estimated along the inclined line from the point S; and that of the product of the parabolic area multiplied into the distance of its centre of gravity, also estimated along the inclined line from the point S.

Explanation of the term stability.

We have said, that when a ship is floating in equilibrium on a fluid, the vertical upward pressure of the fluid acts in the straight line passing through the centres of gravity both of the displacement and of the vessel; but that when she is inclined by the action of any force, as that of the wind, the centre of gravity of the displacement is carried to leeward of its former position; and as the vertical pressure upwards of the fluid still takes place at the centre of gravity of the displacement, its direction should also pass to leeward of the position of the centre of gravity; and thus a force is generated the tendency of which is to enable the ship to recover her upright position. We will now investigate the expression for the value of this force, in order to show the principle on which the actual calculation of its amount in ships is necessarily founded.

Investigation of a General Expression for the Stability of a Ship, and Description of the Method of calculating the Stability.

Fig. 2.



Let ABC (fig. 2) be the midship section of a ship, and AC the line of its intersection with the surface of the water. Suppose *ac* to be the same line when the ship is inclined, K being the point of intersection of the two lines. Now, by the inclination of the ship, of which we have taken the midship section to be a representative, a solid will be immersed on the lee side of the longitudinal axis, and an equal solid emerged on the weather side of the same axis. Call these solids respectively I and E, and suppose them to be concentrated in their respective centres of gravity. Let the horizontal distance between the centres of gravity of these two solids be *b*. Then, since the inclination of the ship has had the effect of taking the solid E from the displacement on the weather side of the middle line, and has added the solid I to the displacement on the lee side of the middle line, the same effect is produced as if the solid E had been transferred to I; and the moment produced by this transfer, which would be *b*I or *b*E, is the moment which is actually produced in the horizontal direction along the distance *b*.

Let G be the centre of gravity of the ship, F the centre of gravity of the displacement when the ship is upright, O

Theory.

the centre of gravity of the displacement when the ship is inclined. Draw OM perpendicular to *ac*. Then, after the inclination, the line OM will be vertical. From F and G draw FT and GV, perpendicular to OM, and from G draw GZ parallel to MO, cutting FT in Z.

Now, when the ship has inclined so that the point O becomes the centre of gravity of the displacement, the upward pressure of the water acts on the then vertical line OM, with a force equal to the weight of the ship, because it supports that weight; that is to say, with a force equal to the displacement, which we will represent by D. But the axis of revolution is the point G the centre of gravity, and GV being drawn from this point perpendicular to the direction OM in which the force acts, D the displacement multiplied by GV, its perpendicular distance from the axis of rotation, will be the force exerted to right the ship, or make it resume its upright position. But, by the construction,

$$D \times GV = D \times FT - D \times FZ.$$

Now $D \times FT$ is the horizontal moment of the displacement produced by the transfer of the solid from the weather to the lee side of the middle line; it is therefore equal to the horizontal moment bI, and consequently we have the effort to right the ship, or the moment of stability, as it is called, $= bI - D \times FZ$.

But if s be taken = sin. of inclination,

$$FZ = s \times \text{rad. } FG,$$

or if $FG = d$, then

General expression. Its value.

moment of stability $= bI - D \cdot d \cdot s$.

Hence, in order to calculate the actual moment of stability of a vessel at a given angle of inclination,

1. Assume an inclined load water-section, cutting the horizontal load water-section at an angle of which s is the sine; and suppose the assumed inclined and the horizontal load water-sections to intersect each other in their common intersection with the longitudinal vertical section of the ship.
2. Find, by the methods of approximation, the solid contents of the two prismatic solids of immersion and emersion, intercepted between the segments of the inclined and the horizontal load water-sections.
3. Find, by the method of approximating to the area of plane surfaces, the area of the above-mentioned assumed inclined section.
4. Find the value of DS (fig. 1), which has been shown to be equal to the difference between the contents of the prismatic solids of immersion and emersion, already found, divided by the product of the area of the assumed inclined section, into s, the sine of the angle of inclination.
5. Through the point S draw a section parallel to the assumed inclined section; find in each vertical transverse section the areas of each of the sections of the true prismatic solids of immersion and emersion; and also find the horizontal moments of these areas from the point S.
6. Find the horizontal distance of the centre of gravity of the whole emerged solid from S, assuming the emerged solid to be equal to half the sum of the two solids of immersion and emersion, which are intercepted between the segments of the assumed inclined load water-section and the horizontal load water-section.
7. Find also the horizontal distance of the centre of gravity of the whole immersed solid from S, assuming the immersed solid to be equal to half the sum of the same two solids of immersion and emersion.
8. Add these two distances together; their sum will be the horizontal distance between the centres of gravity of the solids of immersion and emersion. Take the product of this distance multiplied into half the sum of the solids of immersion and emersion, and we shall have the value of the positive part of the expression for the moment of stability, or the value of bI.
9. The product of three quantities, the displacement, the distance between the centres of gravity of the ship and of the displacement, and the sine of the angle of inclination, will give the value of the negative part of the expression.
10. Subtract the value of the negative part of the expression from that of the positive part, and the remainder will be the value of the expression for the moment of stability of the ship at the given angle of inclination.

Theor

It will be seen that the calculation of the moment of stability of a ship is very laborious. Several of the steps above enumerated in order, will, however, have been already taken for other purposes. The calculations may be considerably shortened by assuming a value for the distance DS, or the distance that the point S is from the middle line of the ship. We have already described the method of ascertaining this distance correctly, but generally it may be assumed to be about two or three tenths of a foot at first; and if the solids of immersion and emersion are not found to be equal, or very nearly so, with that assumption, another point must be taken, either within or without the former, according as the solid of immersion or emersion is the lesser. If e be the difference between the two solids, and a the area of the first assumed inclined section, if x be the perpendicular distance between the true inclined section and the section we have assumed, ax will equal e nearly, or $x = \frac{e}{a}$, which distance must be set off perpendicularly to the assumed section, and we obtain the correct position of the point S.

In order to determine the distance d between the centre of gravity of the ship and the centre of gravity of the displacement, the distance of the centre of gravity of the ship above or below the load water-line must be ascertained. To avoid the labour attendant on obtaining the position of this point by calculation, it may be determined experimentally in each class of ships of war when fully stowed and equipped.

Method of ascertaining the Centre of Gravity of a Ship by Experiment.

On what principle founded.

We shall describe two methods of performing this experiment. The first of these was proposed by Chapman, and he strongly recommended that it should be made on ships of all classes. The principle on which it is founded is as follows. Various weights on board are removed in a transverse direction, so as to cause the ship to incline; and the momentum of the total weight so removed will necessarily be equal to the moment of stability. Now the momentum of the weight removed will be equal to the product of the weights, the distance they are removed in a transverse direction, and the cosine of the angle of inclination; which quantity, therefore, is equal to the moment of stability. If W represent the weights, a the distance they are removed, and c the cosine of the angle of inclination; then, $bI - Dds$ being the expression for the moment of stability, we have this equation,

$$W \cdot a \cdot c = bI - Dds,$$

$$\therefore d = \frac{bI - W \cdot a \cdot c}{Ds};$$

in which d, the distance between the centre of gravity of the ship and the centre of gravity of the displacement, is the only unknown quantity, and may therefore easily be found.

Its appli tion to t Scylla.

We shall now describe the method by which this experiment was applied to determine the centre of gravity of her majesty's ship sloop Scylla, of eighteen guns, and which was originally an eighteen-gun brig. She was lying in Portsmouth harbour in May 1830, under the command of Captain Hindmarsh, at whose request the experiment was performed, by the late Mr Morgan of the School of Naval Architecture, then a foreman of her majesty's dock-yard at Portsmouth, assisted by the writer of the present article.

These particulars are mentioned because it was the first, if it be not the only, example, in this country, of determining the position of the centre of gravity of a ship experimentally.

The draught of water was taken very correctly, the water being smooth, and was found to be, forward eleven feet six inches, abaft fourteen feet ten inches and a half. The depth of the keel and false keels below the lower edge of the rabbet of the keel was, forward one foot nine inches, abaft one foot three inches. The ship was perfectly upright, all the weights, inclusive of the crew, being equally balanced on each side. A large quadrant marked to a scale of degrees, with a plumb attached to the centre, was fixed in the main hatchway, to measure the inclination. The stations of the carronades and long gun on one side were marked on the deck, they were then moved to the other side, keeping them in the same transverse lines; the shot, the hammocks, and the crew, were also passed over to the inclined side, under the same condition. The distance which every weight had been moved was then measured. The weight of the shot moved was known, the weights of the long gun and the carronades were taken from the weights marked on them, and the weights of the men and hammocks were obtained by weighing them. The inclination of the ship was then observed to be 6° 20′. The product of the weights which had been moved, multiplied into the distances they had been moved in a transverse direction, in feet, was equal to 264·5 tons. This moment, multiplied into the cosine of the angle of inclination, was evidently equal to the moment of the stability of the ship.

Let D be the displacement of the ship in tons; I the volume immersed by the inclination, also in tons; b the distance between the volumes immersed and emerged; and d the distance between the centres of gravity of the displacement and the ship.

Then $bI - dD \times \sin. 6° 20' = 264·5 \times \cos. 6° 20'$,

$$d = \frac{bI - 264·5 \times \cos. 6° 20'}{\sin. 6° 20'\ D}.$$

By substituting the values of bI and D obtained by calculation, in this expression, the value of d, the distance between the centre of gravity of the displacement and the centre of gravity of the ship, is obtained.

$$d = \frac{446·2 - 262·8}{50·85} = 3·6 \text{ feet.}$$

The distance of the centre of gravity of the displacement below the load water-line being equal to 3·97 feet, 3·97 − 3·6 = ·37 will be the distance of the centre of gravity of the ship below the load water-line at the time of making the experiment.

When the ship was at Spithead, completely fitted out, with every thing on board that was deficient at the time of making the experiment, and with her provisions and stores for four months, the draught of water was again taken, and found to be, forward twelve feet six inches, abaft fourteen feet ten inches. The weights of all the articles brought on board since the experiment amounted to 33·4 tons, and the moment of these weights calculated above the water-line at the time of sailing was = 193 tons; the height of the centre of gravity of the sails being estimated as in the case of a top-gallant breeze.

The moment of weights below this water-line at the time of making the experiment = 401 tons,

$$\frac{401 - 193}{494·4} = ·42 \text{ feet.}$$

The situation of the centre of gravity of the ship was ·42 foot, or five inches, below the water-line, at the time of sailing.

Cor t- ness f the expe ment dou ul.

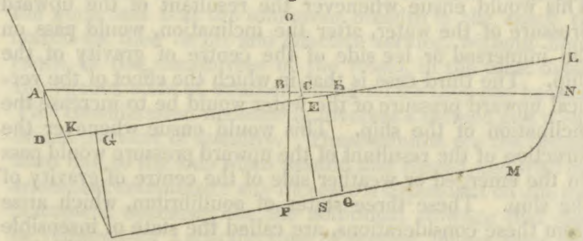
The correction to the result of this experiment which we see had to be made at Spithead, in consequence of the additional weight that had been taken on board after the ship had left the harbour, must, from the great hurry incidental to any observations made at the time of a ship's sailing, throw some doubt on the correctness of the final result; and it would be therefore desirable that it should receive the confirmation of a second trial on some similar ship, before its being assumed as conclusive to be the correct position of the centre of gravity of a sloop of war.

Experimental method when a ship is docked.

The second method was proposed by Mr Abethell, a member of the late School of Naval Architecture, and was published in the second volume of the Papers on Naval Architecture. It is applicable whenever a ship is taken into dock with the under side of her keel deviating from parallelism with the upper surface of the blocks. This is almost always the case; and it also not unfrequently occurs that ships are docked "all standing," and with so large a portion of their armament and stores on board, that the correction necessary to be made to the result which would be obtained by the experiment and investigation about to be described, in order to make that result agree with the circumstances of any additional armament and equipment, would be comparatively easy. We will now quote from the article in question.

"We will suppose, by the falling of the tide in the dock, the after-extremity of the keel to come first in contact with the blocks; then, as the tide continues to fall, the after-body is gradually forsaken by the water, and the fore-body further immersed, a constant equilibrium being maintained between the total weight of the ship and the pressure of the water against the immersed part of the body, until the ship is aground fore and aft. At any intermediate instant the ship may be considered as a lever of the second kind, of which the fulcrum is the transverse line or point of contact of the keel and after-block, and the power and weight the weight of the immersed volume and that of the ship respectively, each acting in the vertical line passing through its centre of gravity. As we can, by mensuration and calculation from the draught of the ship, easily find its weight, that of the immersed volume, and the perpendicular distance of the line of pressure from the fulcrum; in the equation of the moments, the distance of the vertical line passing through the centre of gravity of the ship is the only unknown quantity, which is therefore readily determined. AN (fig. 3) represents the water-line corresponding to the floating position of the ship, and KL the observed water-line just previously to the fore-part of the keel touching the blocks. The line PBO, perpendicular to AN, passes through the centre of gravity of the displaced volume AFMN, and consequently through that of the ship. Draw QH through the centre of gravity of the volume KFML, perpendicular to KL, and FG through the fulcrum F, parallel to QH Then, putting the total displacement AFMN = V, KFML $= v$, and GH $= b$; if the line SEO, parallel to QH, be drawn at the distance GE from G equal to $\frac{bv}{V}$, it will, as well as PBO, pass through the centre of gravity of the ship, which will be in O, the point of their intersection.

Fig. 3.



"To obtain from these considerations a general expression for the perpendicular distance of the point O from the

Theory.

water-line AN, draw AD perpendicular to EG, and meeting it, when produced, in D; and, having calculated the values of AB and GE, put AB $=a$, DE or DG + GE $=d$, and the angle of inclination between the water-lines AN and KL $=\Delta$; then BO $=\left(\frac{d}{\cos.\,\Delta}+a\right)\frac{1}{\tan.\,\Delta}$; which must be set off upon the perpendicular PBO, above or below AN, according as $\frac{d}{\cos.\,\Delta}$ is greater or less than a."

Other methods.

There are several other methods by which the centre of gravity of a ship may be found experimentally. One was proposed by Don Juan d'Ulloa, a Spanish writer on naval science, and a navigator and mathematician of very great eminence, whose works are among the best extant on the subject of the theory of ships. They have been translated into French; and the description and investigation of the experiment for finding the centre of gravity of a ship has been translated into English by Mr Read, in the Essays and Gleanings on Naval Architecture, a periodical work conducted for a short time with great ability by Messrs Laire, Read, and Chatfield, all members of the late School of Naval Architecture. Another method was proposed by a student at the same establishment, since dead, named Barton. This method was published in the fifth number of Papers on Naval Architecture.

Error in the assumption that the vertical pressure necessarily tends to diminish the inclination.

We have hitherto, throughout our investigations, assumed that the vertical pressure upward of the water to support a ship acting in the direction of its resultant, must exert a force tending to resist the force of the wind by which we have supposed the ship to be inclined. We shall now proceed to show that this is not necessarily the case, but that the tendency of this force may not be to act in the manner we have hitherto assumed it as acting; and that its effect is dependent upon the position of the centre of gravity of the ship, the point around which she is supposed to revolve in inclining. There are three cases which may occur. The first is, that the vessel, when acted upon by the force of the wind, may assume a permanent inclination. This permanent inclination would ensue if the resultant of the upward pressure of the water were, after the inclination, still to pass through the centre of gravity of the ship. The second case is that in which the vessel would recover the upright position immediately on the removal of the inclining force. This would ensue whenever the resultant of the upward pressure of the water, after the inclination, would pass on the immersed or lee side of the centre of gravity of the ship. The third case is that in which the effect of the vertical upward pressure of the water would be to increase the inclination of the ship. This would ensue whenever the direction of the resultant of the upward pressure would pass on the emerged or weather side of the centre of gravity of the ship. These three states of equilibrium, which arise from these considerations, are called the state of insensible equilibrium, of equilibrium of stability, and of equilibrium of instability.

Three cases.

On the Metacentre.

A limit to the position of centre of gravity of a ship.

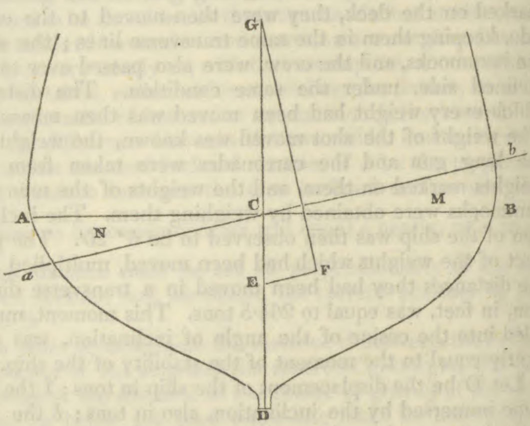
It is evident, from the foregoing considerations, that there is some limit to the height of the centre of gravity of a ship, and below which it must necessarily be placed, in order that the upright position may be recovered; that is, that the ship, when inclined by the force of the wind, may be in an equilibrium of stability. The situation of this point was first investigated by Bouguer, who called it the *metacentre*, which name has been generally adopted by subsequent writers on naval architecture. Its height is determined in the following manner: The vessel is supposed to be inclined through an infinitely small angle of inclination, that the intersection of the new load water-section with that previous to the inclination may not be supposed to deviate from the middle line of either, so that the infinitely small solids of immersion and emersion may be considered to be equal to each other. Then the point in which the new line of direction of the vertical upward pressure of the water will cut the line of direction of the same vertical pressure before the inclination, is the point beneath which the centre of gravity must necessarily be situated to insure the vessel's floating on the water in the equilibrium of stability.

Height of metacentre.

Theo

In order to determine the height of the metacentre above the centre of gravity of the displacement, let the half breadth at the water-line AB of the midship section ADB (fig. 4) $=y$. Let E be the centre of gravity of the displacement before the inclination, F the centre of gravity of the displacement after the inclination, and let ab be the new water-line; then through E and F draw EG and FG respectively perpendicular to the water-lines AB and ab. They will meet each other in some point G. G, the point of their intersection, is the metacentre, and EG is the height of the metacentre above the centre of gravity of the displacement.

Fig. 4.



The triangles ACa, BCb are equal, by the conditions of the construction; and if x be the length of the prismatic solids of immersion and emersion, AC$a\cdot dx$ and BC$b\cdot dx$ are equal, and may be supposed to be concentrated in their respective centres of gravity M and N, MN being by construction $\frac{4}{3}y$. Then the moment of the transfer of the solid of emersion to the position of the solid of immersion $=$ BC$b\cdot dx\cdot\frac{4}{3}y$. Let A$a=$ B$b=b$. But the triangle BC$b=\frac{yb}{2}$, therefore the moment of immersion $=\frac{2}{3}y^2bdx$, therefore $\int\frac{2}{3}y^2bdx=\mathrm{D}\cdot\mathrm{EF}$; but

$$b:y::\mathrm{EF}:\mathrm{EG}\;\therefore\; b=\frac{\mathrm{EF}}{\mathrm{EG}}y.$$

By substituting and multiplying both sides by $\frac{\mathrm{EG}}{\mathrm{EF}}$

$$\int\frac{2}{3}y^3dx=\mathrm{D}\cdot\mathrm{EG},\qquad\int\frac{2}{3}\frac{y^3dx}{\mathrm{D}}=\mathrm{EG}.$$

A meas of stabil

The height of the metacentre is the measure of stability used by the French naval architects, and indeed generally by all since the first investigation of its principles by Bouguer in his *Traité du Navire*. The error in its practical application is, that the investigation involves the erroneous supposition, that the transverse sections of the immersion and emersion are right-angled triangles, and that the horizontal distance between their centres of gravity is two thirds the breadth of the load water-line. These assumptions are only true at an infinitely small angle of inclination, and at such only, therefore, is the height of the metacentre a correct measure of stability. Atwood, who published two papers on the stability of floating bodies, in the Philosophical Transactions for the years 1796 and 1798, was the first who pointed out the error in the metacentric measure of stability, and who proved that it was necessary to involve the actual content immersed or emerged, and the correct distance between the centres of gravity of the solids of immersion and emersion, in the expression, in order to apply it to the measuring the stability of bodies at finite angles of inclination. It is therefore to him that the theory of ships is indebted for the correct solution of the problem on which the stability at finite angles of inclination depends.

Atwood agrees with Bouguer in his general reasoning on the metacentre, and even admits that it may be used at very small angles of inclination, as a sufficiently accurate measure of the stability; but asserts the danger of its application to practice as a measure at all angles. He shows that two ships may have precisely the same load water-section, which, supposing the relative distance between the centres of gravity of the ship and of the displacement equal in both ships, will determine the height of the metacentre to be the same, and consequently, according to the metacentric theory, the stability to be equal; and yet, from a difference in the forms of the ships' bodies within the limits of the immersion and emersion, the moments of stability, when correctly measured, may be very different. But while we state this as the result of Atwood's inquiry, we must observe, that the practical error between the metacentric method of Bouguer, and the certainly correct method investigated by Atwood, is not of any importance for small angles of inclination, especially in large ships; and further, that a constructor who is acquainted with Atwood's investigations, and who is therefore aware of the correct principles on which the stability of ships depends, may safely apply the metacentric method in his practice, as his bodies will be formed in accordance with the results of Atwood's investigations. It will only be in cases of some important alteration from previously existing form, dimensions, or services, that the labour attendant on the calculations involved in Atwood's expression will be necessary.

The question may probably be stated to resolve itself nearly into this. That ships might be built, in which the stabilities calculated by the two methods would vary very considerably; also, that at very great angles of inclination the stabilities of ships, such in form as are sometimes built, would be found to differ very greatly when calculated by the two methods, but that a constructor acquainted with both methods would never construct a ship, using only the metacentric method in the progress of his work, which would be proved unstable if Atwood's calculations were applied to the finished design.

In applying the expression $\int \frac{\frac{2}{3} y^3 dx}{\text{D}}$ to find the height of the metacentre, we may again have recourse to the rules of approximation. The common rule for obtaining the area of a plane surface may be applied, substituting the cubes of the ordinates of the load water-section instead of the ordinates themselves.

The result will be the value of y^3dx, and two thirds of this value divided by the displacement will give the height of the metacentre above the centre of gravity of the displacement.

The reader who wishes to refer to cases of stability as connected with particular forms, should consult Atwood's papers in the Philosophical Transactions, or rather Mr Read's able simplification of them in the Essays and Gleanings on Naval Architecture, and also his Disquisition on the Metacentre, in Papers on Naval Architecture.

On the Principal Dimensions of a Ship.

Dimensions dependent on displacement.

In a ship of war the efficiency of the armament is necessarily the primary object of the design; this must therefore determine the dimensions: also, whether in a fleet or in a single ship, the greatest effective force must be obtained at the least expense; or, as when ships are built, masted, rigged, and their armament completed, all of similar materials, their expenses will vary as their displacements, the object to be attained is the greatest effective force with the least displacement.

Variable quantities to complete load-displacement.

But there is another point involved in the question of the efficiency of the armament, which very materially influences the displacement. It is the time for which a ship is intended to maintain her armament in an efficient state, without other aid than that which she can carry. This brings us to the consideration of the variable quantities which are to be added to those before enumerated, to complete the load-displacement. The crew is dependent on the armament alone, and therefore is included in the term armament. But the provisions for this crew, and the stores for the wear and tear of the ship and the service of the guns, are dependent on the time that the ship is intended to remain at sea without replenishing these resources. It is evident, that the longer this time, the greater must be the displacement, and, consequently, the larger should be the dimensions in proportion to the armament.

Practical advantages attending wide-spread possessions.

It results, from the foregoing reasoning, that the nation with the most wide-spread possessions, and therefore the most frequent opportunities for refitting and replenishing her fleets, has the advantage over all others. For she may maintain equal armaments at less expense, or superior armaments at an equal expense; while she may also avail herself, in the one case, of additional velocity, which may be attained with the diminished displacement.

Many arguments might be deduced from the same considerations in favour of the principle of occasionally designing specific ships for specific services. These of course would only apply to the fleets of those nations which aspire to wide-spreading and predominant naval power.

Length and breadth, under what limitation.

We shall now offer some general remarks on the two dimensions, the length and the breadth. It will be evident, from the foregoing observations, that the minimum length is the space required for the perfectly efficient working of the guns, and that the minimum breadth is the space required for their recoil and effective service, without hindrance to the manœuvres of the vessel, in the most disadvantageous state of weather during which they can be used. This consideration necessarily involves a defined and a sufficient moment of stability. These minima are the dimensions due to the ship when masted and rigged, and with her armament completed: any increase is dependent on the displacement necessary for the additional stowage that may be required for a specific time of service, longer than that time for which the ship, as thus determined, would be adequate. Then the increased dimensions due to this increased displacement being ascertained, under the same conditions of perfect efficiency in the vessel, any increase of one dimension must be followed by a diminution of the other; or the displacement, and consequently the expense, will be above the limit required for the armament.

Effect of increase;

of length,

We shall now proceed to show the effect on the qualities of the vessel, of the separate increase of either dimension; always premising, that in each case all things else are supposed to remain the same, excepting the dimension under consideration. First, then, the length. The displacement, the stability, and the resistance to leeway, vary directly as the length; therefore we increase all these qualities in proportion to the additional length. But we also increase the violence of pitching and 'scending; for the momenta of the weights in the fore and after bodies vary as the squares of their distances from the axis of rotation, consequently we increase the strain on the combinations of the structure; and as the strength to resist this strain varies inversely as the length, we diminish the power to resist this increased strain. By an increase in the length we also increase the effect of the resistance of the water to the rotation of the vessel in the manœuvres of tacking, wearing, and other changes of her course.

of breadth.

By increasing the breadth, and by breadth we mean the whole breadth of that part of the body included in the limits of the immersions and emersions, we increase the stability, which varies as the cube of the breadth. Also, the angular momenta of the weights, estimated from the axis of rotation, vary as the squares of their distances from that axis, and the momentum of the stroke of a wave is increased in the same proportion; therefore the increase of stability is accompanied by increased violence in the motions, and consequent increased strain on the combinations and materials of the structure, and especially danger to the masts, by which the safety of the vessel may be compromised. The stability of a ship being the quality on which the efficiency of her armament is essentially dependent, and which also, by enabling her to carry a press of sail in circumstances of danger, as a lee shore, or an enemy of superior force, is essential to her safety; the only limit to its increase is involved in the consideration of easiness of motion. But if this consideration be neglected, and the breadth be such that the moment of stability in proportion to the moment of sail is so large, or of such sudden increase, that the masts are endangered or the combinations of the structure prematurely destroyed, the object for which a large moment of stability was desirable is frustrated. The breadth, therefore, is limited by easiness of motion.

By increase of breadth we increase the stowage, which varies as the breadth; but since the direct resistance to the progress of the vessel also varies as the breadth, in this case we do not gain increase of stowage without an increase of the direct resistance.

Small ships should have greater relative breadth than large ships.

Having thus pointed out in general terms the effects of an increase either of length or breadth, we shall quote from a very able article in the fifth number of Papers on Naval Architecture, written by Mr Bennet, a member of the abolished School of Naval Architecture, containing some more particular observations on the breadth of vessels in proportion to their armament and in relation to their stability. "The capacities of ships increase as the cubes of their dimensions, whereas the stability increases as the fourth power of their dimensions. The inference to be drawn from this is, that small ships should have greater relative breadth than large ships. This, however, must be understood with certain limitations: it may be a general, but not an universal truth. Were all ships homogeneous; thus, if a navy consisted entirely of corvettes, the corvette of eighteen guns ought to be relatively broader than the corvette of 120 guns: this is a rule without any exception. It may be farther observed from the previous remarks, that the corvette of eighteen guns should be relatively broader than the three-decked ship of 120 guns; but if a ship were built to carry 120 guns on four or even on five decks, her relative breadth should then approximate to, and should most likely exceed, that of the corvette, in order to insure sufficient stability. The consideration of this simple case may tend to elucidate the principles of stability when applied to cases of greater difficulty. If a three-decked ship of 120 guns is to carry the same force on a greater number of decks, her absolute length would of course be reduced; and supposing her breadth to remain the same, the positive part of the expression of stability would be thereby diminished. The displacement, which is one element of the negative part of the expression, would probably remain nearly the same, as the additional weight of topside might counterbalance the reduction of weight occasioned by less length. If the displacement be equal in each case, the draught of water would be increased from the diminution of length; this would lower the centre of gravity of displacement, which, together with the centre of gravity of the ship being raised by the additional weight above the water, would increase the distance between the centre of gravity of the ship and that of the displacement. On the whole, therefore, the positive part of the expression would be diminished and the negative part increased, so that the stability would be less in a ship of the same force and breadth as another ship, but which carried her guns on a greater number of decks.

Least ve sel of e class lia to be de cient in stability.

"Having seen the necessity, in the case of a ship carrying the same number and weight of guns as another ship, but on more decks, of increasing the breadth, in order to avoid a deficiency of stability, we may evidently trace the same principle existing between the largest ship of an inferior class, and the least ship of a superior class, in which, if the number of guns be not equal, it approximates sufficiently to make the application apparent; so that in the several gradations of corvettes, frigates, two-decked ships, and three-decked ships, the least vessel of each class is liable to be wanting in stability, from its small comparative dimensions not sufficiently counteracting the effect of additional decks and guns. In this case, therefore, above all others, particular care should be taken to give sufficient breadth to compensate for a tendency to deficiency in stability; so that, without much liability to error, we may conclude,—

General conclusions.

"1st, That the small frigate should be relatively broader than the large corvette.

"2d, That the small two-decker should be relatively broader than the large frigate.

"3d, That the small three-decker should be relatively broader than the large two-decker.

"Between each of these varieties there will be a certain point, if the expression may be used, where the superior and inferior classes of ships should have the same ratio of length to breadth. This arises from the enlargement of their dimensions increasing the stability in a greater proportion than the weight of additional decks and guns diminishes the stability. Thus,

"4th, The middling-sized frigate should have the same ratio of length to breadth as the large corvette.

"5th, The middling-sized two-decker should have the same ratio of length to breadth as the large frigate.

"6th, The middling-sized three-decker should have the same ratio of length to breadth as the large two-decker.

"As corollaries from the first three observations, we may remark,

"7th, That the large corvette should be relatively broader than the large frigate.

"8th, That the large frigate should be relatively broader than the large two-decker.

"9th, That the large two-decker should be relatively broader than the large three-decker."

Draugh water de pendent locality.

The depth or draught of water is more dependent on local circumstances than on accurate principles. A fleet intended to traverse the Atlantic may have far different draughts of water from the ships of one that is destined for the Baltic. Cruizers for the open seas may be much deeper than those intended to watch an enemy's coast.

May be proxima ed to.

The average light draught of water which a ship will swim at, or the average load draught of water that will be found necessary for her, may be easily and accurately approximated to by means of the calculations of the displacement which have been already explained.

The actual water-line, with the difference of draught of water which it may be considered necessary to insure to the vessel, may also be approximated to in the design of a ship, or approximately determined from the drawing of a ship already designed, on the following principle. Suppose the body of the vessel to be divided, at the vertical transverse section passing through the centre of gravity of the displacement, into two, the fore and after bodies; then, if the depths of the centres of gravity of the displacements of the two parts of the vessel below the assumed water-line be determined, a line joining these centres of gravity will necessarily be nearly parallel to the seat which the vessel will assume in the water.

Tables have been formed by Mr Cradock, a member of the late School of Naval Architecture, for facilitating the stowage of the ballast in ships, in order that they may sail at a determinate trim. These tables, being deduced from various ships in her majesty's service, afford approximations for similar vessels; but when there is a dissimilarity in size and form, we quote from the preliminary remarks to the tables, "in order to place the ballast in such a position, that when all the weights are on board no alteration in it shall be necessary. The difference between the light draught of water, and that to which it may be proposed to bring the ship when fully equipped, being known, the centre of gravity of this part of the displacement may be found. And if through this point a transverse vertical plane be supposed to pass, the ballast must be so placed that its moment from it, together with the moments from the same plane of all the other weights put on board, may be equal to nothing." The length of these calculations is a convincing proof of the value of such approximating tables.

ater.

It is almost an universal custom in all vessels to give a greater draught of water abaft than forward. Occasional attempts have been made to discontinue this practice, as involving a supposed unnecessary increase in the water required for floating a ship; but the increased draught of water for the after-body has been reverted to as essentially requisite in practice.

dvan-
s.

There are several minor advantages which result from this arrangement; such as the more easy and unchecked flow of the water to the rudder, and its consequent increased effect in governing the motions of the ship; also the diminution of the negative resistance which the vessel would otherwise experience from the greater difficulty with which the flow of water would fill the vacuity caused by the passage of the vessel, if the fulness of the after-body were such as would be required to preserve an even draught of water; and again, the adjustment of the resultant of the resistance of the water to that position of the masts which experience has determined to be requisite for the facility of manœuvring the sails. But the principal reason for the inequality in the draught of water appears to be the advantage which results from it to the more easy regulation of the motions of the vessel by an adjustment of the resultant of the resistance of the water on the lee side when on a wind.

This will be more apparent in a future portion of this article, in which we shall consider the forces which act on a ship when in motion. The idea intended to be conveyed is, that the flatness of the after-body along the deadwood may be considered as a reserve of lateral resistance, to be brought into operation whenever the pressure of the water on the lee-bow would otherwise draw the resultant of the water too far forward.

The dimensions of the merchant-shipping of England have been so shackled by the operation of the tonnage laws, that it is in vain to expect to find in their proportions any approximation even to those which experience has proved are most advantageous for safety and for velocity. We take the following table from Hedderwick's Treatise on Marine Architecture, which being the most modern work on the mercantile navy, we presume contains details of the most modern practice.

"Sloop Margaret, 60 tons, breadth to length as 34·8 to 100.
"Smack Regent, 142 tons, breadth to length as 34·2 to 100.
"Smack Matchless, 170 tons, breadth to length as 33·4 to 100.
"Smack Royal Sovereign, 204 tons, breadth to length as 32·0 to 100.
"Schooner Charlotte, 101 tons, breadth to length as 31·5 to 100.
"Schooner Glasgow, 155 tons, breadth to length as 31·0 to 100.
"Brig Down Castle, 149 tons, breadth to length as 30·0 to 100.
"Brig William Young, 303 tons, breadth to length as 28·6 to 100.
"Ship Mary, 368 tons, breadth to length as 27·9 to 100.
"Ship Albion, 505 tons, breadth to length as 25·10 to 100.

"The average depth of the sloops and smacks is about five ninths of their breadth; schooners and brigs, from seven twelfths to three fourths; and large brigs and ships, from three fourths to two thirds."

This immense proportionate depth is the natural result of the old rule for calculating the tonnage; according to which tonnage the worth of the ship was estimated, and all the dues and duties levied. The rule involved only the dimensions of length and breadth, and consequently left the depth to be increased without limit, or rather with no other limit than the depth of the harbours the vessel was destined to trade to. Now, Chapman, in the *Architectura Navalis Mercatoria*, gives an expression to which he says the velocity may be considered proportional: it is $\frac{B^{\frac{1}{2}} \cdot L^{\frac{4}{3}}}{D^{\frac{3}{2}}}$; in which B represents the breadth, L the length, and D the depth to the bilge; from which expression it is evident the depth is the dimension the most detrimental to the velocity. Valuable tables of some of the elements of design of the present classes of merchant-ships have been published by Mr Parsons, formerly of the School of Naval Architecture, under the title of Scales of Displacements.

Investigation of the Forces which act on a Ship when in Motion, as they influence her Form and Qualities.

Preliminary observations.

We have now described the methods by which the several calculations for determining the elements of the design for a ship may be performed; and have also pointed out, in general terms, the dependence of the several principal dimensions upon each other, and their respective influence on the qualities of a vessel. We shall proceed to offer some more particular remarks on the forces of the wind on the sails and of the water on the hull when the ship is in motion, and investigate some of the principal phenomena of their action; as it is only by a consideration of the influence of these forces on the motions of the vessel that the naval architect can form a correct idea of the essential requisites for the design of a ship's body, or the position or proportion of the masts, the area of the sails, and the position of their centre of effort. The investigations into which we shall enter in this portion of the subject may perhaps be found in some cases equally useful to the sailor as to the naval architect, as he will trace in them the means for developing the powers of the vessel he may command, or of obviating by the appropriate remedy any error inherent to her design or equipment.

Questions interesting alike to the sailor and the naval architect.

Pitching and 'scending.

The motion of pitching is generally the most violent action to which a ship is subjected, and the most injurious, both to the connection between the parts of her structure, and the velocity of her sailing. It is the longitudinal motion, caused by the variable support afforded to the body by the waves as the vessel passes over them when on a wind, and by the constant action of the gravity of the unsupported part of the body to recover the state of equilibrium which, before the commencement of the motion, had existed between it and the buoyancy of the fluid. The motion will continue as long as the course of the vessel remains the same in relation to the set of the seas, and as long as the inequality of the surface of the water continues; but when the direction of the wind on the vessel becomes such that she no longer meets and passes over the seas, so that it may be said to act in conjunction with gravity, in offering a constant opposition to the vessel's oscillations, the motion will cease. For these causes, the pitching motion can only exist to any great extent when a vessel is on a wind: then, its force will depend on the degree of inequality of the surface of the water, on the quickness or slowness of the succession of the waves, on the direction in which they strike the bow of the vessel, and on the shape of the bow, as this greatly influences the degree of violence with which it meets the water, and the resistance it opposes to submersion.

may be diminished.

The least injurious action of pitching occurs when the state of the sea is such that the motion of the ship may be supposed to take place round a line passing through its centre of gravity as a fixed axis of rotation; for then the motion may be compared to the oscillations of a pendulum, and its extent may, in a great degree, be regulated by either increasing or diminishing the length of the isochronal pendulum, according as the state of the sea appears to require the oscillations to be made in longer or shorter periods. These effects may be severally produced, by removing weights further from, or by approaching them nearer to, the axis of rotation; that is, by increasing or diminishing the moments of inertia of the fore and after parts of the body round its axis of rotation.

But it is, as has before been said, only in some states of the sea that the pitching motion in a vessel can be compared to the oscillations of a body round a fixed axis of rotation passing through its centre of gravity, and where the moments of inertia of both the fore and after bodies oppose the motion; for, under many of the circumstances of heavy seas, though, at the commencement of the motion, the axis of rotation may pass through the centre of gravity of the ship, it will pass abaft it as the wave passes aft. In this case, then, the moment of inertia of the body before the axis of rotation, which, when this axis passed through the centre of gravity, was equal to the sum of the particles in that body multiplied by the squares of their distances from the axis of rotation, will become, at any instant afterwards, when the axis of rotation shall have passed abaft the centre of gravity, increased, by the difference between this quantity and the sum of the products of the particles in the then fore-body, multiplied by the squares of their distances from the new axis of rotation; consequently the moment of inertia of the fore-body will be constantly increasing until the end of the motion, while the moment of inertia of the part abaft the axis of rotation will be constantly diminishing, under the same limits; that is, the force which has an injurious effect on the violence of the pitching increases, while that which diminishes its violence decreases. As the direction of the motion of the waves is opposed to that of the vessel, the momentum with which the bow of the ship will meet the sea at the expiration of the motion, is equal to the sum of the momenta of the bow and the sea; and this impulse is often so great in practice, as to be sufficient completely to check, for several seconds, the motion of the vessel in her course. Frequent recurrences of these shocks must, therefore, not only be extremely injurious to the strength of the fabric of the ship, but must materially affect her progress through the water, and may even, in some situations, involve her safety, from the increased liability of shipping seas, especially in deep-waisted vessels; and also, unless a ship can contend with advantage against a head sea, her chance of escaping the danger of a lee shore must be considerably diminished, as in such a situation her safety would in a great measure depend on the possession of that property.[1]

Evils resulting from its violence.

Angular momentum.

From these considerations, it is evident that every alteration which can be made to diminish the extreme violence of this motion, when it takes place under the circumstances which have been described, either by lessening the moment of inertia of the fore-part of the ship, or by giving that part the form which will the most conduce to render its impact with the water more gradual, must be advantageous with respect to the velocity, to the preservation of the strength of the ship, and even to the increasing the safety of the crew. But since the bow of a ship is subjected to shocks of such a violent nature, it must necessarily consist of a vast combination of materials to insure an adequate degree of strength to resist them: great care, however, should be taken that there be not more weight than this renders absolutely necessary. These considerations point out at once one limit to the position of the masts; for it is evidently desirable that the weight of the fore-mast and the pressure of the head-sails should act with as little injurious effect in increasing the violence of the pitching, as is consistent with the necessity for head-sail; this will be better understood as we proceed with our investigation of the various forces which act on a ship when in motion.

A limit t the positions of t masts.

Resultan of forces.

When the ship is under sail, there are two forces acting on it; the one, the force of the wind on the sails, to propel the ship; and the other, the resistance the water opposes to her motion. These forces, immediately the ship has acquired the velocity due to the strength of the wind, are equal, and, as is the case with all forces, may each be reasoned on as if acting on only one point of the surface over which its effect is diffused. This point is that in which, if the whole force were to be concentrated, its effect would be the same as when dispersed over the whole area: it is usual to call these, "resultants of forces," and the points on which they are supposed to act, "centres of effort."

Centres effort.

Action of wind on t sails, and water on the hull.

From what has been before said, the resultant of the force of the wind on the sails, and the resultant of the force of the water on the hull, are equal; the one acting on the weather side of the ship, in the direction into which the force of the wind resolves itself, and the other opposed to it, acting on the lee side, in the direction into which the force of the water resolves itself; and their effect is necessarily in proportion to their distance from the centre of gravity. If they are equally distant, they will destroy each other, and the ship will remain at rest with respect to the line of its course; if the resultant of the resistance of the water passes before the resultant of the wind, the ship will turn to the wind; but if the resultant of the wind passes before that of the water, the effect will be the contrary, and the ship will fall off from the wind. In either case it will be necessary to equalize the forces, by the action of the water on the rudder, on its lee side, to bring the resultant of the water more aft, and on its weather side to destroy a part of the effect of the wind. This is the principle of the action of the wind on the sails, and of that of the water on the hull, with respect to the course of the ship through the water; and it is on these considerations only that the various alterations can be regulated, which it may from time to time be necessary to make in the trim either of the sails or of the ship; and hence the accurate determination of the positions and directions of these two forces is a point of great importance in naval architecture. The position of the centre of effort of the wind on the sails may be found under certain reservations; and that being known, enough is determined to lead to correct conclusions on the other circumstances attendant on the subject.

---

[1] Mr Henwood, a member of the late School of Naval Architecture, has advanced some new views on the subject of the pitching and 'scending motions in ships, which we think of sufficient importance to endeavour to explain. They are as follow,—that these longitudinal motions of a ship depend both on the form of the immersed part of the body, and on the positions of the various weights which compose the lading or equipment; and the form of a ship, and the positions of the weights, determine the situation of the centre of gravity through which the axis of the pitching and 'scending motions passes. It is the position of this point or axis which, Mr Henwood has stated and endeavoured to show, might and ought to be so determined in all ships, that the pitching and 'scending motions would be diminished to the lowest possible degree.

In order to construct a ship on this principle, the fore-part of the ship, viz. that before the centre of gravity, would be formed in the usual manner; but the after-part would be constructed so as to have precisely the same cubic content as the fore-body, and its centre of gravity at the same distance from the centre of gravity of the ship as that of the fore-body.

In the stowage of a ship thus constructed, the weights must be so disposed that one half of the total weight of the ship and her equipment may be on each side of the vertical and transverse plane, through the centre of gravity.

The object intended to be gained by the fulfilment of the above conditions is, that a ship should perform her longitudinal or pitching motions exactly as she does her lateral or rolling motions; and that as there is the same tendency to roll either side equally deep, so there should be a like tendency of the fore and after ends to pitch and 'scend. The pitching and 'scending motions would, Mr Henwood considers, thus be reduced to a minimum, and the velocity of sailing retarded in the least possible degree.

This proposed desideratum in the construction of ships is irrespective of the form of the midship section, or of the water-lines, &c. It is simply the constructing of one end of a ship upon the basis of the other end, so as to insure the attainment of the object in view,—the least possible degree of pitching and 'scending.

tre of rt of d before tre of vity of p,

In order to find the distance of the centre of effort of the wind on the sails before the centre of gravity of the ship, the moment of each sail is calculated by multiplying its area by the horizontal distance of its centre of gravity from that of the ship; the sum of the negative moments, or those abaft the centre of gravity of the ship, is then subtracted from the sum of the positive moments, or those before the centre of gravity of the ship; the remainder is then divided by the total area of the sails, and the result gives the required distance of the centre of effort of the wind on the sails before the centre of gravity of the ship. The situation of this point with respect to the length of the vessel must determine in a considerable degree the positions of the masts; for experience has proved, that it is among the most essentially requisite good qualities of a ship, that she shall carry a weather helm.

er- es positions of ts.

ct of der.

It does not at first appear evident why the rudder should have more effect on the ship when it meets the water on one side of the middle line, than it has when put to an equal angle on the other side; the reason has, however, been partially explained by several writers on naval architecture, from the consideration of the direction of the motion of a ship through the water. Among these Don Juan has been the most explicit. The reasoning he pursues is as follows: That as a great portion of the force of the wind, in all oblique courses, tends to drive the ship bodily to leeward, and as this effect cannot by any means be wholly destroyed, the true course of the ship is not in the direction of its own middle line, but in that of a line passing from the lee bow to the weather quarter, parallel to the ship's wake; and he supposes that the fluid meets the rudder in the direction of this line of lee-way, both on the lee and weather side of the ship; and that therefore, when the helm is a-weather, the angle of incidence of the fluid on the rudder is equal to the sum of the angle of lee-way, and the angle made by the direction of the rudder with the middle line of the ship; while, when the helm is a-lee, the angle of incidence is only equal to the difference between these two angles, and that therefore, when they are equal to each other, this difference vanishes, and all action of the water on the rudder ceases; and this, under Don Juan's suppositions, would occur when the rudder was in the direction of the line of lee-way. And hence, as the most advantageous general position for the rudder is that in which, by offering no obstacle to the passage of the water, it offers no resistance to the velocity of the ship, and yet may by the least variation from this inactive position be brought to act effectively, it follows, either that Don Juan's reasoning is incorrect, or that the most advantageous general position for the helm should be a-lee. But experience proves, that with the helm a-lee, the rudder would not have the effect on the ship which has been described; therefore, although Don Juan's reasoning shows the main principle of the greater effect of the rudder when it is to leeward of the middle line of the ship, than when it is inclined at an equal angle to windward of the middle line of the ship, it is insufficient to account for the fact, that the general position of the helm should be a-weather; indeed his reasoning, on the contrary, proves that it should be a-lee; which error arises from the incorrectness of the assumption which he makes, that the fluid meets the rudder on the weather side of the ship, in the direction of the line of lee-way. Now when a ship is on a wind, her course, we have said, is along a line passing from the lee bow to the weather quarter, which line is also that of the direction in which the ship impinges upon the particles of water. Each particle of water, after its impact with the lee bow, will be reflected from it in a direction which, according to the law of the collision of bodies, will form an angle with the bow, and consequently with a tangent to the bow at the point of impact, and would therefore, if produced to cut the middle line of the ship, form a greater angle with that line than would be formed by this tangent to the bow at the point of impact, produced to cut the same line.

soning on n.

The results do not agree with practice.

Error in the preliminary assumption.

Correction of this error.

This will be the case with the whole of the particles of water which come in contact with the lee bow, and along all that part of the lee side of the ship, a tangent to which, if produced, would meet the line of the ship's course at any finite distance before her bows; so that as a ship progresses along the line of her course, since these motions may all be supposed to become constant, her lee side will pass through water having an absolute motion with respect to the motion of the ship, the direction of which forms an acute angle with the middle line of the ship produced aft.

We will now consider the effect of the accumulation of the water at the bows of the ship, either to diminish or to increase this angle. Since there must be a constant tendency in the particles of water which compose this accumulation to recover their level, there must also be a constant run of particles from the apex of this accumulation to its base; the ultimate direction of the sum of all these motions would therefore evidently form an acute angle with the middle line of the ship produced forward; and consequently, by the composition of forces, the action of the particles of water to recover their level would increase the angle which the direction of the motion of the water makes with the middle line of the ship produced aft.

By extending the same reasoning to the motion of the water on the weather side of the ship, a very little consideration will show that the principal effect the passage of the ship through the water would have on the particles of water on that side, would be to cause them to rush aft in a direction inclined towards the middle line of the ship, in order to fill the vacuum created under the weather quarter by the passage of the vessel along the line of lee-way.

We may therefore assume that the particles of water have a motion at the stern of the vessel, the direction of which forms an acute angle with the middle line of the ship produced aft, which angle will evidently be dependent on the fulness or the fineness of the after-part of the body, and on the angle which the line of the ship's course, or that of the lee-way, makes with the middle line of the ship, consequently the inactive position of the rudder will be when it forms this angle with the middle line of the ship, that is, when the rudder is to leeward, and consequently the helm a-weather. And this position should be the theoretic limit of the degree of weather helm a ship should carry, as in any other position there must be a force acting on the rudder, which must increase the resistance the ship expe-

Experience confirms these views.

Weather helm.

riences in her passage through the water. A practical confirmation of the correctness of this principle, and of the fact that this generally advantageous position of the rudder is a-lee of the middle line of the ship, may be drawn from the common observation, that when a ship is in good trim, the helm, being a-weather, has a very perceptible tremulous motion, which must arise from the rudder's being in a position in which it is not acted upon on either side by any constant force. This method of considering the direction of the flow of the water to the rudder considerably diminishes the estimate of the excess of its effect on the lee side of the rudder over that on the weather. But there are several other considerations which operate in increasing the effect of the weather-helm. From the direction in which the water flows past the ship, there will be a much greater reduction of pressure on the weather side of the rudder when the helm is to windward, and therefore a greater positive pressure on its lee side to turn the ship, than will occur under the opposite circumstances, or when the helm is a-lee. Also, the broken and disturbed state of the water on the after-part of the weather side of the ship, and the consequent various degrees of resistance it opposes, must lessen its effect when the helm is a-lee.

Ships with lee helm leewardly.

Effect mistaken for cause.

It has been said to be proved by practice, that ships which carry lee-helms cannot be weatherly, that is, will fall faster to leeward than those which carry weather helms. But though the fact is correct, the reason assigned is in some degree mistaking the effect for the cause. It has before been said that a part of the force of the wind acts in driving a ship bodily to leeward; of course its effect will be greater or less in proportion to the lateral resistance opposed to it, and the ship which opposes less lateral and greater longitudinal resistance to the water than another, will in the same period of time have fallen farthest to leeward, and the line of her course will have made a larger angle with her middle line, by which the effect of the water on the after-part of the lee side is increased, while that on the fore-part, both of the lee and weather sides, is diminished, and the helm must consequently be kept less a-weather. A practical proof of the correctness of this reasoning may be drawn from the practice of the merchant-vessels, which are generally, from form, more leewardly than men-of-war. They have their fore-mast placed much nearer the centre of the ship than is usual in sharper and finer formed bodies. This has evidently arisen from the operation of the cause above mentioned, which has shown that they require the resultant of the effort of the wind on the sails to be proportionately farther aft to insure their carrying a weather-helm. From this reasoning it is evident that, under some circumstances, it may be the leewardliness of the ship which causes her to carry a lee-helm; and that when such is the case, the defect might be remedied, not only by the usual methods of placing the masts farther aft, and altering the draught of water, but by increasing the lateral resistance by the addition of false keel, or by greater depth in the water.

Disadvantage of lee helm.

There is another disadvantage arising from a ship's carrying a lee-helm, which is, that the action of the water on the weather side of the rudder acts in conjunction with the force of the wind in forcing the ship bodily to leeward; while, on the contrary, when the helm is a-weather, the action of the water on the rudder is in opposition to the force of the wind.

Effect of sail on helm.

Having now pointed out wherein the necessity consists, that a ship should carry a weather helm under all circumstances, and explained the principles by which the position of the helm is governed, it next remains to consider in what manner this position of the rudder may be affected when the ship is under sail. This is the more necessary, because there are occasions in which ships that generally carry good helms will carry them a-lee; it therefore also remains to be examined whether this defect might not either be wholly removed, or at least ameliorated.

Ardenc

The ardency of a ship, which is her tendency to fly to the wind, depends, as has been explained, on the relative positions of the resultant of the effort of the wind on the sails, and the resultant of the resistance of the water on the hull. A consideration of the effects produced on these forces, when a ship is under way, will lead to the object of our inquiry.

Passag a body a fluid.

Its effe on ard

Effect of crease of clinatio

When a body passes through a fluid, it causes an accumulation of the fluid to take place towards its foremost extremity, and a depression of the fluid towards the opposite. The degree of this accumulation and depression will depend on the velocity with which the body passes through the fluid, and its increase must necessarily have a great effect in drawing the position of the resultant of the water farther forward; therefore, from this cause, a ship becomes more ardent as her velocity is increased. Also, as the ship on a wind inclines by the force which communicates motion to her, an increased surface of the bow is immersed; while, from the fulness of its shape both above and below the original water-line, the angle of incidence with which it meets the water does not undergo much alteration: consequently the tendency of the inclination is to draw the resultant of the water forward, in so far as the shape of the bow is involved. By the inclination, the effect of the water on the after upper portion of the lee-side is so diminished as to be almost destroyed, in consequence of the decrease of the angle of incidence with which it meets the water, arising from the sharpness of the after-body under the lee quarter, which, by the inclination, is made to approximate to a horizontal plane: consequently the tendency of the inclination is to draw the resultant of the water forward, in so far as the shape of this part of the body is involved. That lower portion of the after-body which is nearly vertical when the ship is upright, and, until the vessel is on a wind, is subjected to little more than the mere friction of the water, immediately that a ship is on a wind offers great lateral resistance, even after the inclination of the ship; and it is this lateral resistance of the after-body which, being brought into action simultaneously with the increased direct resistance of the fore-body, tends to prevent too great an effect from that direct resistance in drawing the resultant of the water forward, and therefore acts in aid of the helm in preventing the ship from flying up into the wind, and thus obviates the necessity of such violent action of the rudder as would be injurious to the velocity of the ship.

The larger the area of this portion of the after-body, the less necessity therefore is there for extreme and consequently detrimental action of the rudder under the circumstances of increased wind and inclination. It appears, however, that in ships generally, the inclination increases the ardency, by drawing the resultant of the water forward.

Of incre ed imme sion of t ter-body

This train of reasoning shows us in what the advantage consists which arises from the increased immersion given to the after-extremities of ships; and it enables us to form the following general rule, as an approximation to correctness of principle in determining the increased draught of water to be given to the after-body. The difference in draught of water should increase or diminish in proportion as the area which a ship offers to direct resistance is great or small in relation to the area offered to lateral resistance; or, in general terms, the difference of draught of water in ships, *cæteris paribus*, should vary directly as the ratio which the breadth bears to the length.

Sails assumed to plane su faces.

The position of the centre of effort of the wind on the sails is calculated under the supposition that the sails are plane surfaces, and equally disposed with regard to the longitudinal axis of the ship; but when a ship is on a wind, as the force of the wind acts in a direction oblique to the surface of the sails, a greater proportion of the sail is carried to leeward of this axis, and the whole sail assumes a curved surface, the curvature of which increases from the weather to the lee side. From these circumstances, the centre of

eory.

E t of th cur-va e.

effort is in fact carried gradually farther aft as the action of the wind takes place on the sails. Also, as the force of the wind inclines the ship, the centre of effort of the wind on the sails is carried, by this inclination, over to the lee side, by which, as also by the effect produced on the resultant of the water, which has been before mentioned, the distance between them is farther increased. It therefore appears that, the quantity and disposition of the sail set remaining the same, the ardency will increase as the force of the wind increases, and diminish as that force diminishes; but as it is found in practice that ships very generally require their helms a-lee in light winds, although it is evident that the several circumstances which have been mentioned as creating the tendency of ardency must still exist in a small degree, it would appear that the ardency must increase and decrease in a faster ratio than the force of the wind. Now, as the direct and lateral resistances vary respectively as the squares of the velocities of the ship in these two directions, it is evident that the lateral resistance will diminish in a quicker ratio than the direct resistance, and that, consequently, as the wind decreases, the angle of lee-way, or that of the ship's course, will be increased, which, it has before been proved, will draw the resultant of the water aft, and diminish the ardency; therefore the increase and diminution of the ardency of a ship will be in proportion to the difference of the ratios of increase and decrease of the direct and lateral resistances.

O crease o nd.

M s of di ishing le elm.

From the causes which have been assigned for a ship's carrying a lee helm in light winds, it is evident the defect may be lessened by all those means of trimming either the sails or the ship, which have been mentioned as tending to increase the distance of the resultant of the water before the centre of effort of the wind.

Le helm de dent on ate of the a,

But when a ship's carrying a lee helm is occasioned, as it sometimes is, by the state of the sea, the waves of which, strike the ship on the weather bow, and in their passage cause a great immersion of the lee quarter, any attempt to bring the resultant of the water forward would, from the consequent greater immersion of the bow, and the necessary addition to the momentum, increase the effect of the impulse. The evil may be lessened by diminishing the quantity of head-sail, which will both bring the centre of effort of the wind aft, and diminish the violence of the pitching; and also, if the inclination of the ship were increased, that, by increasing the effect of the water on the lee bow, and diminishing its effect on the lee quarter, might in some cases prove advantageous.

and n the po on of the asts.

In heavy weather, ships under a small quantity of sail very generally carry slack helms, partly in consequence of the position of the centre of effort of that sail, and partly owing to the state of the sea. Under these circumstances it is generally impossible to carry enough of after-sail to remedy this defect; and to trim the ship by the head would be only to increase it, on account of augmenting the pitching. There is therefore no other remedy than that which would arise from such an original disposition of the masts as would render the power of creating a balance between the effects of the sails more easy. But here we would observe, that before making any alteration in the position of the masts, great caution is necessary; for possibly one of the first requisites in a ship is, that she should work quickly, which quality depends on the proportion of sail before and abaft the axis of rotation, and not on the position of the centre of effort of the whole surface of the sail. Therefore no alterations can be made in the position of the centre of effort of all the sails, or in the positions of the masts, unless due consideration be given to the effect they would have on these proportions.

Too reat arde y.

It may now be necessary to observe, that a ship may, on some occasions, be too ardent. In addition to the alterations which will suggest themselves in this case, from what has been already said, it may be observed, that as the curvature of the sails, and the inclination of the ship, both tend to increase the ardency, it may be diminished by taking in sail, especially those which, from their greater breadth, assume a greater degree of curvature.

Theory.

Erroneous objections.

It is sometimes objected by practical men, that trimming a ship according to the principles laid down by theory, has not the effect which was to have been expected; but this often arises from an ignorance of the necessary degree of trimming, or from a mistaken notion of the effect which a certain degree will produce. In order, in some measure, to obviate this difficulty, the following table is given. It contains the weight which it will be necessary to move a distance of forty feet, either aft or forward, to produce an alteration of one foot in the trim of a ship. The length and breadth of the ship are given in the table, merely as being more correct data for the comparison of size than the class of the vessel or the number of guns.

Class of Vessel and number of Guns.		Length.	Breadth.	Weight to be moved a Distance of Forty Feet.
		Feet.	Feet.	Tons.
First rate............	120	205·25	54·50	112
Second do............	84	192·25	51·44	90
Fourth do............	60	174·00	43·67	58
Fifth do..............	46	159·70	40·50	38
Sixth do..............	28	120·20	33·67	22
Sloop..................	18	111·25	30·50	14

If any other alteration in the trim be desired, it may be deduced from the results given in the above table, by a simple proportion. And since the effect produced on the centre of effort of the sails, by taking in or setting any sail, may be estimated in the manner described in the course of these remarks, the alterations necessary to be made in order to produce any desired effect may be easily determined. Another source of error may arise from the various rakes of the masts; from which the angle of incidence, and consequently the force of the wind, which is as some function of the sine of the angle of incidence, varies considerably for the sails of each mast; and if the trim of the ship be altered, there must be a corresponding effect produced in this angle; by which the relative proportions of the force of the wind on the several sails will be altered, as will also its total effect on all the sails.

Bracing of the yards.

Most of the writers on naval architecture have considered the problem of determining the angle which should be formed by the yard with the keel, under the different circumstances of wind. Don Juan, whose highly scientific and thorough practical knowledge entitles his opinions to more than common attention, on a subject in which the researches of theory require to be aided by the deductions from experiment, has determined these angles for a ship of sixty guns, and has also given some general rules to guide any variations from them. When this ship was close-hauled, with all sail set, he found that the angle the yard should make with the keel should be 28° 47′, and with the wind on the quarter, 50° 11′; but when the wind was so high that only a small quantity of canvass could be set, these angles were respectively increased to 40° 42′ and 56° 21′. He also arrives at the general conclusion, "that, the greater the quantity of sail set, the less should be the angle made by the yard with the keel;" and also, as he makes the relation between the direct and lateral resistances enter into his investigations, "the sharper and the more adapted for velocity a vessel is, the smaller should be the angle made by the yard with the keel;" consequently frigates and smaller vessels should, under similar circumstances, have their yards braced sharper than line-of-battle ships; and again, "that the nearer the sails approach to plane surfaces, the less should this angle be."

Erroneous position of fore-mast.

According to the present positions of the masts of a ship, the sails on the fore-mast are generally not capable of being so sharply braced as those on the main-mast; but as theory and practice, as may be instanced in fore-and-aft rigged vessels, concur in fixing the limits to which it would be desirable to brace the yards, within even what can generally be attained on the main-mast, much of the force of the wind on the sails of the fore-mast must be lost; and as this less sharpness of bracing, common for the yards on the fore-mast, is even found to be necessary in many ships, to enable them to carry their helm sufficiently a-weather, it would appear that the position of the fore-mast is too far forward, and that moving it aft would be advantageous; besides the good effect it would have, as has been shown, in diminishing the violence of the pitching motion.

The position of the fore-mast appears to have remained nearly the same as it was determined in the early part of the last century, although many of the reasons which then fixed it at about one ninth the length of the ship from the stem have ceased to exist. Our ships are now longer, and there is consequently room for working the sails, without those of one mast coming in contact with, or destroying the effect of the wind on, those of the other. The after-parts of the hull above water are very considerably reduced, and do not therefore render so great a proportion of head-sail necessary to counterbalance the effect of the wind on them. The bodies of the ships are, from the increase of the dimensions, much finer abaft, and consequently the resultant of the resistance is farther aft. From these considerations, and from the fact that it is found that complaints are made of ships carrying lee helms, it appears not improbable that the generality of our ships would be improved by an alteration in the position of their fore-masts.

The forms of our ships, and indeed those of some of the more modern French vessels of which we are possessed, have approximated more to that recommended by Chapman, and since his time adopted by the Swedes and Danes, than to that of the old French bodies, which were for such a series of years the chief guides of the English ship-builder. The marked characteristics of the old French body were, a flat floor, with a sharp and, beneath the water, hollow fore-part, and a comparatively very full after-part. The character of the Swedish construction is, the rising floor, full fore-body, and extremely fine after-body. The generality of the English ships of the present day are built with the rising floor, and approximating more, towards the extremities, to the Swedish than to the old French characteristics. It seems therefore but reasonable that the positions of the masts of our ships should partake of the principle which appears to have dictated the alteration in the form of their bodies. With this view, and for a general example as to the positions of ships' masts, and of the ideas of various constructors, the following table has been formed, of the positions of the masts of the vessels contained in Chapman's "large work," of some of the present Swedish ships, of the various classes of English ships, and of several other vessels which have either some peculiarity in this feature of their construction, or are remarkable for an excess of any good or bad quality dependent on it. The other data in the table are necessary for completing the comparisons which may be made.

[1] An increase in the rakes of the stems.

[2] The fore-mast raked four inches in ten feet.

[3] On an even keel.

eory.

tion of s in hant- s.

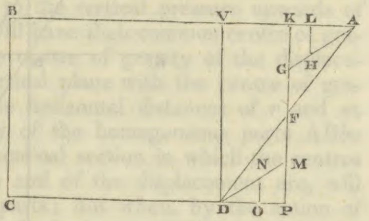
From this table it will be seen that the position of the fore-mast in the ships of different rates in her majesty's service is considerably more forward than in the Swedish ships; and that in Chapman's experimental frigate, the Chapman, it is remarkably far aft. The Comet, as altered, after being sold out of the service, the Pearl, built by Mr Sainty, and the four merchantmen, are proofs of the practice, before alluded to, of the merchant builders; the alteration in the position of the masts of the Comet having taken place under the direction of the late Mr Fearnall, a gentleman of high character for a knowledge of his profession.

The stations of the masts in the ships built after the designs of the present surveyor of the navy, Sir William Symonds, approximate very nearly to those of the Swedish ships; the main and mizen masts are even rather farther aft in proportion to the length of the ship.

C rect p t from w h to m sure the p ions of th masts.

The positions of the masts are given, in the table, in relation to the foreside of the rabbet of the stem; but though this point has been adopted in compliance with the usually received custom, and to avoid the introduction of a feature which might have rendered comparisons more difficult, a more correct method would be to estimate the station of the masts from a point K (fig. 5), at a distance AK from the foremost extremity of the load water-line; such that, KP being drawn perpendicular to the load water-line, it shall intersect AD, the foremost boundary of the longitudinal vertical section of the vessel, in such a manner that the resistance to angular motion round an axis of rotation BC, passing through the centre of gravity of the vessel, shall be equal to the triangles AKF and DFP, DP being the lower boundary of the false keel produced.

Fig. 5.



The point K being determined for all ships, comparisons might be correctly made of the positions of the masts in vessels with the most dissimilar rakes of the stem; which feature, from its effect on the resultant of the resistance, must have a considerable influence on the positions of the masts, and which cannot be estimated in distances measured from any other point.

The following proof will show, that if BK be taken equal to the arithmetical mean between BA and CD, the point K will be determined sufficiently correctly for all practical purposes.

From D (fig 5) draw DV perpendicular to AB. Bisect KF and FP in G and M, and draw AG and DM. Take AH $= \frac{2}{3}$AG, and DN $= \frac{2}{3}$DM; then H and N will be the respective centres of gravity of the triangles AKF and DPF. From H and N draw HL and NO perpendicular to BA and CP. Let $AB = a$, $CD = b$, $AV = a - b = c$, $AK = x$, $AL = \frac{2}{3}x$, and $VD = h$. Then the resistance to rotation of the triangle AKF is proportional to the area

$$\text{AKF} \times \text{BL} = \frac{\text{AK} \cdot \text{KF}}{2} \cdot \text{BL}.$$

$$\text{Now, AK : KF :: AV : VD} \therefore \text{KF} = \frac{hx}{c}$$

$$\text{the resistance} = \frac{hx^2}{2c} \cdot \left(a - \frac{2x}{3}\right).$$

And in the same manner, the resistance of DFP is

$$= \text{area DFP} \cdot \text{CO} = \frac{\text{DP} \times \text{PF}}{2} \cdot \text{CO},$$

$$\text{PF : DP :: DV : AV} \therefore \text{PF} = \frac{h \cdot \overline{c - x}}{c}.$$

Theory.

Hence the resistance $= \frac{h \cdot \overline{c - x}|^2}{2c} \cdot \left(b + \frac{2}{3}\overline{c - x}\right)$, and these resistances must be equal to each other,

$$\therefore x^2\left(a - \frac{2x}{3}\right) = \overline{c - x}|^2\left(b + \frac{2}{3}\overline{c - x}\right)$$

$$\text{and } x = a - \sqrt{a^2 - \left(bc + \frac{2c^2}{3}\right)};$$

from which expression, if numbers be substituted for the several quantities, it would be seen that, assuming BK equal to the arithmetic mean between AB and CD, will be sufficiently correct.

Recapitulation.

The method of finding the horizontal distance of the centre of effort of the sails, either before or abaft the centre of gravity of the ship, has now been explained as being a necessary element to be determined in forming the design of a vessel. The effect which the action of the water on the hull, and of the wind on the sails, would have, under various circumstances, on the relative positions of this point with respect to the centre of gravity of the ship, has been described, and also the necessity of regulating the trim of the ship and sails according to the state of the sea and wind, that the most advantageous proportionate distance may be preserved between them.

Height of effort of sails.

We shall now investigate the principles on which the determination of the vertical height of the centre of effort of the sails above the centre of gravity of the ship depends. This problem, though it is one which may be classed among those of which the "solution resolves itself to laws of nature which are yet imperfectly developed," may be solved by induction from experiment; and we shall show that sufficient data may by this means be obtained, to render the abstract principles of science, on which it depends, practically available, so as to overcome the difficulties which at present oppose themselves to the perfecting one of the most important elements of naval architecture, the sizes and proportions of the masts and yards.

Moment to resist inclination.

In describing the circumstances attendant on the inclination of a ship from the upright position, we have said that the moment of the force exerted by the vertical pressure to resist the inclination will be measured by the perpendicular distance from the centre of gravity to the direction of the resultant of the vertical upward pressure of the water after the inclination, which necessarily passes through the centre of gravity of the displacement. We have hitherto called this the moment of stability, but it may be more properly termed the moment of hydrostatical stability, as being dependent on the laws of the equilibrium of fluids. But if the force which has been described as inclining the ship round its centre of gravity also communicates motion to the system, another moment of stability will be generated by the resistance which the water opposes to the motion. This resistance, as has been before explained, may be supposed to act in a resultant, the direction of which will necessarily depend on the form of the vessel. Now, if the form be such that the direction of this resultant will pass above the centre of gravity of the ship, its moment, estimated from that centre of gravity, will act in conjunction with the moment of hydrostatical stability before described, and will diminish the inclination; a contrary effect will ensue if this resultant passes below the centre of gravity. Now, if the moment of this force to diminish the inclination were equal to the moment of the force which acts to produce it, the ship would remain in a vertical position; but if it be not equal to it, the inclination will be caused by the action of the excess of the moment of the inclining force over the moment of the force acting to diminish the inclination, and the ship will revolve until this part of the inclining force shall be destroyed by the moment of hydrostatical stability which will be generated by the inclination. The moment of sta-

Hydrostatical stability.

Hydrodynamical stability.

bility resulting from this cause may be called the moment of hydrodynamical stability, as being dependent on the motion of the body in the fluid, that is, on the relative motion of the fluid. This does not agree with the usual definition of hydrodynamical stability adopted by writers on naval architecture, as that also involves the elements of the hydrostatical stability in its terms; but it is thought that keeping each moment of stability distinct, by referring it wholly to its own generators, tends to simplify the consideration of them; and also, the explanation of the principles on which the height of the centre of effort of the sails depends may by the same means be divested of some obscurity.

Equilibrium of wind on sails, and water on hull.

Now, when, by the action of the wind on the sails, motion is communicated to a vessel from a state of rest, at first the effort of the wind on the sails is much greater than that of the water on the hull, and by the effect of the excess the velocity of the vessel is accelerated: but the velocity with which the wind acts on the sails is diminished in proportion as the velocity of the vessel is increased, therefore also the force with which it acts on them is gradually lessened: but as the velocity of the vessel increases, the resistance the water opposes to its motion is also increased; consequently the two forces, the effort of the wind on the sails, and the resistance of the water on the hull, will ultimately become equal to each other; and as they act in opposite directions, the vessel will, by the laws of motion, continue to move uniformly in the direction of its course with the last acquired velocity; and this velocity will be in proportion to the moving force, that is, to the force of the wind and the area of sail exposed to its action, or, if the force of the wind be supposed constant, will be in proportion to the area of the sail.

Uniform motion of the vessel.

Limit to height of centre of effort.

From what has been before said, it is evident that the moment of sail must be in proportion to the stability of the ship; and since the velocity will be in proportion to the area of sail exposed to the action of the wind, the height of the centre of effort of the sail should be determined from the consideration of acquiring the greatest effective area of sail of which the powers of the ship will admit.

Bouguer, from reasoning on the facts which have been explained, which are, that when a ship has acquired an uniform velocity in any direction, the action of the wind on the sails to propel her in that direction becomes equal to the resistance opposed to her motion by the water, and that the moment of the resistance, calculated from the centre of gravity or of rotation, that is, the moment of hydrodynamical stability, subtracted from the moment of the action of the wind on the sails, estimated from the same point, will give the force by which the ship is inclined, conceived the idea that the sails of a vessel might be so disposed that she should maintain the same vertical position when under sail as when at anchor. This he proposed to effect by adjusting the sail in such a manner that its centre of effort should be situated in a point, which he has named the "*point velique*," and which he describes as being such, that when the centre of effort of the sails coincides with this point, the moment of the force of the wind to incline the ship will be wholly destroyed by the moment of hydrodynamical stability. But such an arrangement of the sail is not practically applicable to the cases in which the direction of the action of the force of the wind is oblique to that of the course of the vessel; for, from the small proportion which the breadth of a vessel bears to her length, the moment of hydrodynamical stability will, under these circumstances, be less than when the directions of the wind and of the ship's course coincide, while the resultant of the effort of the wind will act at the same height above the centre of gravity of the ship in either case; therefore Bouguer only insists, that since the moment of the hydrodynamical stability cannot, consistently with other circumstances, be made to destroy the whole of the effort of the wind to incline the ship, care should be taken that these two forces should be so proportioned to each other, that a sufficient moment of hydrostatical stability may be acquired to resist the excess of the moment of the wind on the sails over the moment of hydrodynamical stability, without too great an inclination of the ship.

Point velique.

Not practically applicable in oblique courses.

Of impor ance in d rect cours

But when the direction of the wind coincides with that of the course of the vessel, it is of great importance that the change from a state of rest to one of motion, or rather from one velocity to another, should be performed without any longitudinal inclination towards either extremity, and that the vessel should preserve that seat in the water which has been determined as most advantageous with reference to the longitudinal position of the centre of effort of the sails.

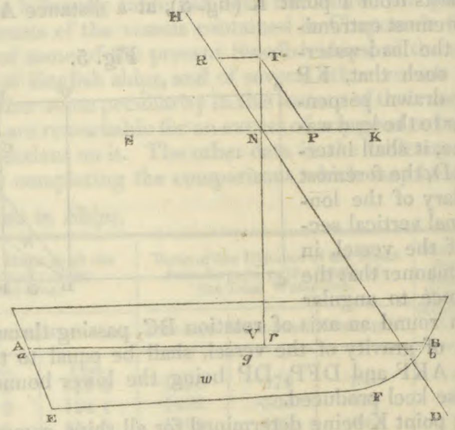
Bouguer reasons false premises, y valuable

The course of reasoning which Bouguer has pursued to determine the position of this point involves suppositions which are at variance with the facts attendant on a vessel's motion through the water, and therefore the conclusion at which he arrives is erroneous; still, as an elucidation of the principle, his method may be advantageously explained.

Investig tion of p sition of *point velique.*

He supposes DH (fig. 6) to be the direction of the resultant of the direct and vertical resistances experienced by the fore-part of the vessel AEFB, moving in the direction AB; and the line SK to be the direction of the resultant of the whole force of the wind acting on the sails. Let it meet DH in N. Now since, when the ship has acquired an uniform velocity, the forces which oppose the motion are equal to those which produce it, and as these forces act horizontally and destroy each other, the forces which remain must be vertical. Take NR and NP to represent in quantity and direction the force of the water on the bows, and of the wind on the sails; then complete the parallelogram NRTP, and join NT; NT will represent, in quantity and direction, the force remaining after those parts of the forces NR and NP, which are equal and opposite, are destroyed; and therefore NT will act in a vertical direction to lift the ship. But though this will be the direction of the action of NT on the vessel, its effects may also be to produce a rotatory motion round her centre of gravity. This will depend on the position of the point N, the intersection of SK and DH. If we suppose the direction DH to be constant in position, and SK to vary in position according to the height of the sails, we shall see, that when the masts and sails are high, the direction SK will cut the direction DH at a point near the stern; and therefore the action of the force NT taking place so near one extremity of the vessel, and one side of the centre of gravity, will tend to immerse the opposite extremity. On the contrary, if the masts and sails are low, the direction SK will intersect the direction DH more near to the bows of the ship, and the action of NT being before the centre of gravity, will raise the fore and immerse the after part; and this in-

Fig. 6.



eory.

clination will continue until the force which causes it is destroyed by the moment of the hydrostatical stability generated by the inclination. From this, Bouguer concludes that it is only when the masting is of such a height that the direction SK intersects DH at a point at some mean distance between the bows and stern, and at which neither of these effects will be produced, that the ship will have no tendency to longitudinal oscillation, and the only effect of the force NT will be to lessen the part of the ship which is immersed in the water when she is at rest; and this point he has called the *point velique*. Bouguer determines the position of this *point velique* in the following manner. From *r*, the centre of gravity of the load water-section, as being nearly coincident with the centre of gravity of the lamina, AB*ba*, of the vessel which is lifted by the action of the force NT, the vertical line VT is drawn, and the point N in which it intersects the direction of the resultant of the resistance of the water to the bows will be the point through which the horizontal line SK, representing the direction of the action of the wind on the sails, should pass, in order that the ship may move in the direction of its course without a depression of either extremity. In order to prove that this will be the case, he supposes the displacement ABFE of the ship to be made up of the two homogeneous parts AB*ba* and *ab*FE; and therefore, when the ship is only subjected to the vertical pressure upwards of the fluid, these parts will have their common centre of gravity, which will be the centre of gravity of the displacement, in the same vertical plane with the centre of gravity of the ship. The horizontal distances of *r* and *w*, the centres of gravity of the homogeneous parts AB*ba* and *ab*FE, from the vertical section in which the centres of gravity of the ship and of the displacement are, will be inversely as those parts; but when, by the action of the force NT at *r*, the displacement is diminished by the quantity AB*ba*, the vertical pressure upwards will be diminished by that same quantity, and will act at *w*, the centre of gravity of the new displacement *ab*FE, with a force equal to the weight of *ab*FE; therefore, the forces being inversely proportionate to the distances of their action from the common centre of gravity of the ship, and both acting upwards in a vertical direction, will maintain the ship in equilibrio round that centre of gravity. This reasoning of Bouguer on the position of the point N is incorrect in its application to practice. It depends on the supposition, that when by the force of the wind motion is communicated to the vessel, she will rise in the water from the effect of the action of the force NT, and the water-line AB will become *ab*, the displacement being diminished by the quantity AB*ab*. It is not enough to satisfy the conditions of Bouguer's reasoning, that NT should exert an effort at *r* equal to diminishing the displacement by the quantity AB*ba*; for unless the diminution of the displacement actually takes place, the position of its centre of gravity cannot be affected in the manner assumed in the reasoning, but will continue in the vertical section passing through the centre of gravity of the ship; and then, by the action of the force NT at *r*, the ship will revolve round the centre of gravity *g*, until, by the motion of the centre of gravity of the displacement, incidental to the revolution, a moment of hydrostatical stability is generated equal to the moment of NT to incline the ship. Now it is proved from experiment that the displacement is actually greater when a ship is in motion than when she is at rest; therefore, reasoning on the supposition of its diminution is inapplicable to practice. There would be an alteration in the position of the centre of gravity of the displacement resulting from this increase, which might either act in opposition to, or with the effect of NT, to incline the ship, according to the relative form of the body above the original water-line.

T error of uguer.

But it is evident that the principal error made by Bouguer throughout the investigation of the position of his *point velique* is, that it is conducted with reference only to the resultant of the positive resistances which the vessel experiences, instead of to the resultant of both positive and negative resistances. Chapman, while he adopts Bouguer's views on the existence of some limit to the situation of the centre of effort of the sails above the centre of gravity of the ship, has avoided this error, and has investigated its position from the data of the total resistance experienced by the ship. He first determines the quantity and direction of the mean resultant of both the positive and negative resistances of the water; then, since the force of the wind must be equal to the resistance of the water opposed to it, if the directions of the resultants of these two forces were exactly opposed to each other, their moments, estimated from the centre of gravity of the ship, would be equal, and consequently the force of the wind would have no effect in making the ship revolve round its centre of gravity; therefore, if the surface of the sail was perpendicular to the resultant of the direct and vertical resistances experienced by the ship, there would be no limit, arising from these considerations, to the height at which the centre of effort of the sails might be placed; for, whatever might be its position in the line of direction of the resultant of the resistances of the water, the moments, estimated from the centre of gravity of the ship, would be constantly equal, since the perpendicular distance between that point and the directions of the actions of the forces would remain constant, however the force of the wind, and consequently the resistance of the water, might be increased or diminished. But since the directions of the wind and of the course of the vessel are both horizontal, and the sails are placed nearly at right angles to the horizon, the action of the force of the wind, and its moment round the centre of gravity of the ship, to counteract the moment of the resistance of the water, must be estimated in a horizontal direction; and consequently the height of the centre of effort of the wind on the sails must be measured on a vertical line drawn from the centre of gravity of the ship, and must be such that the horizontal moment of the wind shall be equal to its moment, estimated under the supposition that its action is in a direction opposed to that of the resultant of the resistances of the water, when it will have no tendency to depress either extremity of the vessel.

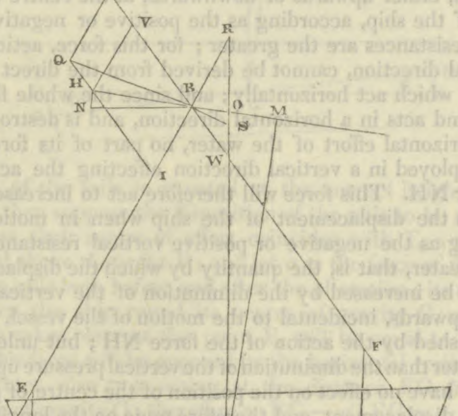
Theory.

He neglects the negative resistances. Chapman has avoided the error of Bouguer.

Chapman's investigation is as follows: Suppose DF and EC (fig. 7) to represent respectively, both in quantity and direction, the resultants of the direct and vertical resistances against the fore and after parts of the vessel. Produce

Chapman's investigation.

Fig. 7.



DF and CE to intersect each other in B; then on DB produced take $BV = DF$, and on BC take $BI = EC$; complete the parallelogram VBIH, and BH will represent, in quantity and direction, the resultant of the whole of the direct and vertical resistances against the fore and after parts of the ship; and BH, multiplied into GM, GM being drawn from the centre of gravity G of the ship, perpendicular to BH produced, will represent its moment to make the ship revolve round its centre of gravity. The centre of effort of the sails must therefore be at such a height that the moment of the wind, estimated from the centre of gravity of the ship, may be equal to this moment. If HM represent the line of direction of the effort of the wind on the sails, the force of the wind acting in that direction will be represented in quantity by HB; but as the action of the wind is horizontal, and is equal to the horizontal effort of the water, if BH be resolved into BN and NH, then BN represents, in quantity and direction, the horizontal resistance of the water, and NB in the same manner represents the horizontal effort of the wind; and if GO be drawn from G perpendicular to the horizon, meeting HB in O, we have, from similar triangles, HBN and OGM, $NB \times GO = HB \times GM$; that is, O, the point in which a vertical line passing through the centre of gravity of the ship intersects the direction of the resultant of the resistances of the water against the fore and after parts of the ship, is the correct height at which the centre of effort of the sails should be placed, that the ship's horizontal water-line, when she has acquired an uniform velocity, may not be affected by any change in the force of the wind.

The point found by Chapman not the *point velique.*

This point O does not fulfil the conditions of Bouguer's *point velique*, as it only determines the position of the centre of effort of the sail as to height above the centre of gravity of the ship; for the moment of sail acting in a horizontal direction, estimated above that centre of gravity, will be the same at whatever point in a horizontal line passing through O the centre of effort may be placed; therefore this point O may be more properly called the height of sail. The position of the centre of effort of the sails in a horizontal line at this height of sail, will depend on the considerations which have been explained in a former part of this article. It may therefore differ very considerably from that determined by Bouguer, not only in its vertical, but in its horizontal position.

From this investigation of Chapman's, it evidently appears, that unless BH coincides with NB, that is, unless the resultant of the resistances of the water is horizontal, there will be a force NH or HN acting in a vertical direction, either upwards or downwards, at the centre of gravity of the ship, according as the positive or negative vertical resistances are the greater; for this force, acting in a vertical direction, cannot be derived from the direct resistances, which act horizontally; and since the whole force of the wind acts in a horizontal direction, and is destroyed by the horizontal effort of the water, no part of its force can be employed in a vertical direction affecting the action of HN or NH. This force will therefore act to increase or diminish the displacement of the ship when in motion, according as the negative or positive vertical resistances are the greater, that is, the quantity by which the displacement would be increased by the diminution of the vertical pressure upwards, incidental to the motion of the vessel, will be diminished by the action of the force NH; but unless NH is greater than the diminution of the vertical pressure upwards, it will have no effect on the position of the centre of gravity of the displacement, and therefore none on the longitudinal inclination of the ship. The force HN, acting in conjunction with the diminution of the vertical pressure upwards, will affect the position of the centre of gravity of the displacement in the same manner as that affects it, that is, dependent on the relative form of the body above the water. Therefore in this case the ship may have a slight tendency to longitudinal oscillation, even though the centre of effort of the sails be placed at the height of sail, as determined by Chapman; but this will not affect the correctness of Chapman's principle, and a ship may be easily constructed with such a form at the parts about the surface of the water, that this inconvenience will not occur.

Case in which l gitudin oscillat may en

Now, if we suppose BV and BI to be given in position, the force NH or HN will depend, in quantity and direction, on the proportion between BV and BI, that is, on the proportion of DF to EC. Now when BH coincides with NB, or when the direction BH of the resultant of the water is horizontal, the force NH or HN vanishes; therefore, if we suppose HB to coincide with BN, then HB is parallel to CD; and the angle VBH will be equal to the angle BDC, and the angle BCD will equal the angle $HBC = VHB$. Now $VH : VB :: \sin. VBH : \sin. VHB :: \sin. BDC : \sin. BCD$; and since $VH = BI = EC$, and $BV = DF$, therefore $EC : DF :: \sin. BDC : \sin. BCD$; consequently we have, that the positive and negative vertical resistances are equal to one another, and the direction of the resultant of the resistances of the water will be horizontal, when the resultant of the direct and vertical resistances of the water on the bows of the vessel is to the resultant of the direct and vertical resistances on the stern, inversely as the sines of the angles which the respective directions of these resultants make with a horizontal line.

General theorem

The extremities of a vessel of the usual form may, for the purpose of determining the proportion between the direct and vertical resistances which they experience, be considered as planes moving obliquely in a fluid, and consequently the proportions between the direct and vertical resistances will depend on the angles of inclination which the surfaces of these extremities make with the direction of the vessel's motion, that is, with a horizontal line; and the sum of the direct resistances on either extremity will be to the sum of the vertical as the cosine to the sine of the angle of inclination; consequently, as long as the inclinations of the bow and stern to a horizontal line remain unchanged, this proportion between the direct and vertical resistances experienced by those parts respectively, that is, the proportion of DK to KF, and of LC to EL, will be invariable; and therefore, as far as these considerations are involved, the directions of the resultants DF and EC will remain constant, whatever alteration may take place in their relative proportion to each other, arising from any increase or diminution in the velocity of the vessel.

Propor between direct a vertica sistance invarial

Since, when the direction of the resultant of the water is horizontal, $EC : DF :: \sin. BDC : \sin. BCD$, then $EC \cdot \sin. BCD = DF \cdot \sin. BDC$; now let us suppose the proportion of DF to EC to be altered, so that $EC \cdot \sin. BCD$ will be greater than $DF \cdot \sin. BDC$, that is, let us suppose the comparative proportion of DF to EC to be increased.

Produce DV to P, and make BP to BI in the increased proportion of DF to EC, complete the parallelogram BPQI, and draw the diagonal BQ; BQ will represent the direction of the resultant of the resistance of the water, after the alteration of the proportion between DF and EC.

Produce QB to S, then the angle $PBQ =$ the angle DBS, and since BP is parallel to IQ, the angle PBQ is equal to the angle IQB, and the angle IHB is greater than the angle IQB; consequently the angle DBM, which is equal to the angle IHB, is greater than the angle IQB, that is, the angle DBM is greater than the angle DBS, and S, the point in which the direction QB cuts the vertical line GO, will be within or below the point O; therefore GS will be less than GO. If EC, that is, BI, had been increased in proportion to DF or BV, the point S would, in the same manner, have been found to be above the point O; consequently, from this we may deduce the following

eory.

eral
rem.

general proposition, that as the proportion which the resultant of the direct and vertical resistances on the bows of a vessel, bears to the resultant of those resistances on the stern, is greater than the proportion which the sine of the angle made by the resultant of the after-resistances with a horizontal line, bears to the sine of the angle made by the resultant of the fore-resistances with a horizontal line, the height of sail will be diminished, and as this proportion is diminished, the height of sail will be increased. Now when DF is infinite in comparison with EC, that is, when the negative resistances vanish, BQ will coincide with BP, and the height of sail will be at W, the point in which the vertical line drawn from the centre of gravity of the ship intersects the direction of the resultant of the positive resistances. But if DF vanishes in comparison with EC, BQ will coincide with BI, and the height of sail will be at R, the point in which the vertical line drawn from the centre of gravity intersects the line BC; consequently the points R and W will be the limits between which the position of the height of sail must be situated. The directions of the resultants of the resistances on the bow and stern being known, the position of this point within these limits will depend upon the velocity of the ship, in as far as that velocity affects the ratio which these resultants bear to each other. And since the negative resistance depends on the degree of vacuum which the vessel creates by the velocity of its passage through the water, it will evidently be very inconsiderable as long as the velocity continues small. In fact, this is found to be the case experimentally, as is also that, after certain limits, this negative resistance increases in a greater ratio than the velocity. We may therefore draw the general conclusion, that the less the velocity of the ship is, the nearer will the height of sail approximate to that of its lowest limit; and, on the contrary, the greater the velocity of the ship, the nearer will this point approach its highest limit. But as we are not yet sufficiently acquainted with the laws of the motion of fluids to determine the ratio of the increase or decrease of the positive and negative resistances experienced by bodies in their passage through the water, we cannot ascertain how near the ultimate position of the height of sail with the greatest velocity which the vessel can acquire will approximate to the limit which has been assigned to it.

true
er-line.

One circumstance which may affect the height of sail remains to be noticed; this is, the deviation of the apparent water-line of the ship when she is in motion, from her horizontal water-line, which is occasioned by the accumulation of fluid at the fore-part of the ship, and the depression of it at the after-part, that is incidental to the motion of a body on a fluid. This will vary in degree in proportion to the velocity of the ship. Now if this addition to the one and diminution from the other of the resisting surfaces alter the proportions between their respective vertical and direct resistances, the directions of the resultants of the resistances on these surfaces, which depend on these proportions, will also be altered. If the extremities of the vessel were formed by plane surfaces, neither the accumulation nor the depression would alter the directions of the resultants of the resistances, since the angles of incidence would be the same for every part of the surfaces; but as the extremities of the vessel are curved surfaces, the effect produced on the direction of the resultants of their respective resistances will depend on the relative inclination to the horizon of the curve of that part of the body beneath the horizontal water-line, and of the parts above or below the water-line, which will be affected by the accumulation and depression of the water. Since the lower parts of the vessel's body, both forward and abaft, are those which are generally most inclined to the horizon, it is probable that the direction of the resultant of the resistances on the bow is lowered by the accumulation of the water against them, and that the direction of the resultant of the resistances to the stern is rather raised by the depression of the water at that part. At the same time it must also be observed, that, by the effect of the accumulation, the centre of effort at which the resultant of the resistances against the bows acts will be raised, while, by the effect of the depression, that at the stern will be lowered.

Theory.

The position of this point will determine the height above the centre of gravity of the ship, at which the common centre of effort of the sails should be placed, not only when the directions of the wind and of the ship's course coincide with each other, but also whatever may be the direction of the ship's course with regard to that of the wind; for, under all circumstances, that portion of the force of the wind which acts in propelling the ship in the direction of her course, will be subject to the same laws which govern the action of the whole force of the wind when it acts in that direction.

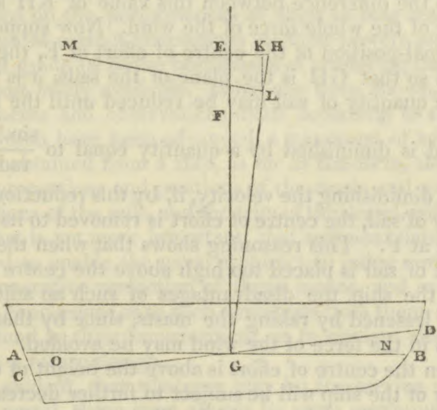
Addition or diminution.

It is also evident, that it is not only necessary that the centre of effort of the surface of those sails which are usually set, and for which the position of the height of sail is generally recommended to be estimated, should coincide with this point; but also, that when additions are made to the quantity of sail set, care should be taken to preserve the common centre of effort of the whole surface as nearly at this same height above the centre of gravity of the ship as is possible.

Velocity may not increase with increase of sail.

It is frequently observed that a ship's velocity does not increase or decrease in proportion to the additional quantity of sail set or taken in. It is evident, from the principles which have been explained, that these apparent anomalies must arise from the mal-position of the centre of effort of the sail; and, in fact, it is even possible that the velocity of a ship may be decreased by the addition and increased by the diminution of sail, if the centre of effort is improperly placed. That this may be the more evident, suppose AB (fig. 8) to be the water-line of a ship, when the centre of effort of the sails is situated at the correct height of sail GF; then suppose the disposition of the sails to be so altered that their centre of effort coincides with E, a point situated above the point F; and let $a =$ the force of the wind on the sails both before and after the alteration; its moment to turn the ship round its centre of gravity G, when its action takes place at the point E, will be equal to $a \cdot EG$, and this force will be opposed by the horizontal resistance of the water, also $= a$, acting at the distance FG from the centre of gravity G; therefore $a \cdot EG - a \cdot FG = a \cdot EF$ will be the force exerted by the wind to make the ship revolve round G, its centre of gravity, and immerse the bows; and the inclination will continue from the effect of this action until the moment of hydrostatical stability, which it will generate, becomes sufficient to counteract it. It should

Fig. 8.



here be observed, that by the difference which the inclination of the ship will make in the angles of incidence of the water on the bows and stern, the correct height of sail, after the inclination, will most probably not coincide with F, but the alteration arising from this circumstance in the position of this point will depend on the form of the vessel's body.

When the force $a \cdot EF$ is destroyed, suppose the water-line to coincide with CD, then from G draw GH, making with GE the angle EGH equal to the angle of inclination DGB; take GH = GE, then H will be the position of the centre of effort E of the sail after the inclination, and the angle BGH will represent the inclination of the plane of the sails to the horizon, they having been supposed to be vertical before the inclination of the ship. Now from H draw HM horizontal, and take MH to represent the whole force of the wind acting in that direction, at the points H and F; then from M draw ML perpendicular to GH; and from L draw LK perpendicular to MH; MK will represent the horizontal force of the wind acting to propel the ship in the direction of its course, when the centre of effort of the sails is at E. Since MH represents the quantity of this force when the centre of effort of the sails is at the true height of sail F, KH will represent that part of the horizontal force which is lost by the mal-position of the centre of effort; and if MH, the whole force of the wind, be assumed equal to radius, then from similar triangles MHL, LHK, we get the value of KH equal to the square of the sine of the angle of inclination divided by the radius, when radius is equal to the whole force of the wind. Therefore, if the removal of the centre of effort from its correct position at the height F had been accomplished by an addition to the quantity of sail set, instead of by an alteration in its disposition, unless the increase of MH, the force of the wind arising from the increase in the area of sail set, was greater than this value of KH, which represents the force lost, the velocity must be diminished instead of being increased, by the addition to the force of the wind; since its effective force to propel the ship would be diminished by a quantity equal to the difference between this value of KH and the increase of the whole force of the wind. Now suppose that by the mal-position of the centre of effort at E, the ship is inclined so that GH is the plane of the sails, it is evident that the quantity of sail may be reduced until the force of the wind is diminished by a quantity equal to $\frac{\sin.^2 EGH}{\text{rad. } MH}$, without diminishing the velocity, if, by this reduction in the quantity of sail, the centre of effort is removed to its correct position at F. This reasoning shows that when the centre of effort of sail is placed too high above the centre of gravity of the ship, the disadvantages of such an adjustment may be lessened by raking the masts, since by that means the loss in the force of the wind may be avoided.

If centre of effort of sail be above height of sail.

When the centre of effort is above the height of sail, the velocity of the ship will be subject to further decrease from the increase of resistance which will result from the immersion of the full parts of the body forward, and the consequently greater area of midship section. Also, in the case which has been supposed of the plane of the sails being vertical before the commencement of the action of the wind, when the longitudinal inclination EGH takes place, a part of the action of the force KL will act to increase the displacement, and consequently the resistance. This disadvantage may also be diminished by raking the masts.

Excess of moment of sail over moment of hydrodynamical stability.

There are other circumstances arising out of the longitudinal inclination of the ship, caused by the excess of the moment of the wind on the sails over the moment of hydrodynamical stability, which are disadvantageous to the good properties of the ship. The equilibrium which ensues between the excess of the moment of the wind and the moment of hydrostatical stability, which has been described as being generated by the inclination, will not be constant, as every increase or decrease in the force of the wind will cause an increase or decrease in the moment of stability, which must be obtained by a corresponding change in the inclination; therefore a ship in which the centre of effort is placed above the true height of sail, will be subject to an alteration in her water-line at every change in the force of the wind; and it will, owing to this circumstance, not only be impossible to adjust the longitudinal position of the centre of effort to any fixed trim of the ship which may have been found to be advantageous, but it will be equally impossible to determine the best longitudinal position for this point, after the ship is in a state of motion, since her trim will be subject to constant change.

Centre effort b low hei of sail.

If the centre of effort, instead of being supposed to be situated above the true height of sail, be considered to be below that point, the immersion will take place at the after-extremity of the ship, from the action of the excess of the moment of the resistance of the water. It must also be observed, that there will be this difference in the two cases. When the centre of effort is above the height of sail, at every increase in the force of the wind the ship will, from the increased immersion of the bows, fly up to the wind, while the effect of the immersion of the after-part will be to make her fall off from it. The ill effects which have been described as attendant on the mal-position of the centre of effort of the sails with respect to the height of sail, though they cannot be removed while the cause exists, and which may consist in the improper proportions of the masts and yards, can in some cases be diminished by an alteration in the disposition of the weights on board the ship. If, instead of supposing the ship to incline, from the action of the force of the wind at the point E, we suppose the effort of this force to produce the inclination to be counteracted by the removal of a weight (b) from a point N at the fore-part of the ship, to another point O at the after-part, then the ship will be maintained in a state of equilibrium by the action of the two equal forces $a \cdot EF$ and $b \cdot NO$; and she will therefore move without longitudinal inclination, as long as the force of the wind remains constant; but any alteration in that force must be counteracted by a corresponding alteration in the position of the weight: also, when, from the action of the water on the hull, the ship acquires an angular velocity, the angular momentum will be increased by that of these two forces, which may both be considered as weights acting at their respective distances from the centre of gravity of the ship. It is therefore evident, that an error in the position of the centre of effort of the sails cannot be advantageously remedied by any alteration in the disposition of the weights in the ship, except in peculiar cases of smooth water; and further, if the error be that the centre of effort is above the height of sail, the ship will labour under the disadvantage of a diminished area of sail, since the moment of sail must be in constant proportion to the moment of stability; and if the centre of effort is too low, the ship may not be able to obtain all the advantage of motive power that her stability would admit of her applying.

Disadva tages of mal-pos tion of centre of effort.

Centre effort a true hei of sail.

It appears, therefore, that unless the centre of effort of the sail be placed at the height of sail, a ship, however good her form, and the properties connected with it, may be, and whatever may be the care bestowed to render those properties most efficient, will labour under very serious disadvantages; while, on the contrary, a correct adjustment of this element, and a knowledge of the principles on which that adjustment depends, will place it in the power of a commander to obtain a maximum of advantage from the powers and properties of his vessel, since it will enable him to acquire the greatest possible efficient action from the motive power at his disposal.

As was before said, the determination of the height of sail must be classed among those problems of naval archi-

Di ulties at dant on prac- ti ppli- ca of fo oing pr ples m e ov ome.

tecture which, labouring under the difficulties attendant on our imperfect knowledge of fluids, cannot be attained by theory alone. It will now be shown that, by the aid of theory, sufficient deductions may be made from experiment to remedy its practical insufficiency. Throughout the foregoing considerations, the sails have been reasoned on as if they were plane surfaces. If this were the case, their centre of effort would coincide with their common centre of gravity; but, from the flexibility of the materials of which they are made, the sails become, when acted upon by the force of the wind, curved surfaces. However, from the whole surface of sail with respect to height being composed of several such surfaces, the error arising in practice from assuming the height of the common centre of gravity of the whole surface to be the height of the centre of effort, will be very inconsiderable; therefore, in practice the centre of effort of the sails may be represented, with respect to height, by their common centre of gravity.

Since we know, from the principles which have been explained, that when the centre of effort of the sails is at the true height of sail, the trim of the ship will not be subjected to alteration by any increase or diminution in the force of the wind, the height of sail for any trim may be determined by experiment, by first bringing the ship to that trim when she is at rest, and then adjusting the sails so that her water-line when in motion may be parallel to this trim. This being admitted, it is evident that, by proceeding on the principles already explained in this article, the maximum of advantage arising from the correct position of the centre of effort of the sail may be insured, by first ascertaining, from experiment and observation made with reference to the longitudinal position of the centre of effort with respect to the centre of gravity of the ship, the most advantageous draught of water, and then determining the correct height of sail with respect to that draught of water.

The observations necessary to effect these objects will require considerable patience and attention; but it must be considered that they will not only enable a commander to derive the greatest possible advantage from the means at his disposal, but that they will afford correct data for perfecting those means. The following observations may suffice to explain the principle which should be pursued. The draught of water previous to sailing should be observed; and an instrument which will correctly measure the angle of inclination should be fixed, in reference to this water-line, so that by means of it every deviation from this trim may be exactly known. This is rendered absolutely necessary, because, when a ship is in motion, her correct trim, that is, her horizontal water-line, cannot be observed, in consequence of the accumulation and depression of the water which is caused by the motion. In fact, any alteration made in the trim of the ship or the sails, founded on observations made with reference to the apparent water-line, might be extremely hazardous, and certainly would not produce the results expected, as the position of this water-line depends wholly on the circumstances which are in immediate operation. Having the instrument fixed, when the ship has acquired a uniform velocity observe the alteration which has taken place in her trim, as, until the velocity is uniform, the trim will be influenced by the force which accelerates the velocity. Then, if her longitudinal oscillations or her pitching motions appear to be only influenced by the state of the sea, the centre of effort is correctly placed at the height of sail. Therefore the height of the centre of gravity of the surface of sail set, will give the height of sail. But if at every change in the force of the wind the vessel experiences a sudden increase of longitudinal oscillation, observe by the instrument its nature and degree, and make such a change in the adjustment of the sails as the foregoing principles have shown to be necessary; and when the tendency to increased longitudinal oscillation ceases, find the height of sail by calculating the height of the centre of gravity of the surface of sail then set. In this manner the correct height of sail for any trim may be found; while, by observing at the same time the comparative qualities of the ship when at each of these trims (after the height of sail is determined for it), that trim of the ship and sails may be determined at which a maximum of advantage may be derived from the inherent good qualities of the ship, as far as the perfection of the *matériel* will admit, that is, as far as the position and proportion of the masts, yards, and sails, are adapted to the elements of the construction of the ship's body; while from knowing the best trim of the ship, and the true position of the centre of effort under the several circumstances of wind and sea, the naval architect will be in possession of sufficient data to make such alterations in the *matériel* as shall then insure a maximum of advantage with a maximum of the means. In fact, correct observations of this nature would go very far to remove much of the difficulty which theory, in its application to some points in the practice of naval architecture, at present labours under.

Recapitulation of principles.

The laws which govern the mutual action of the wind and water on a ship when she is in motion have now been explained, principally as they affect her equilibrium round a vertical or a horizontal axis of rotation; because by pointing out the various states of equilibrium which result between the action of the wind on the sails and the water on the hull, we are enabled to show the effects which may be produced on the qualities of the ship by modifications in these equilibrio; either by the use of the helm, by alterations in the trim of the ship, in the quantity of the sail set, or in the disposition of that quantity, so that in the various changes which may take place in the state of the wind or of the sea, the qualities of the vessel may either experience the least possible injurious effect, or the greatest possible degree of benefit, according as the tendency of the change may be injurious or beneficial. In pursuing this train of reasoning, we have also endeavoured to explain in what manner the principles that govern the mutual action of these forces may be made available in directing such observations on the performances of ships as may lead to the formation of correct conclusions on their powers and qualities, and guide us to the best means of rendering these qualities most easily available. It has also been shown, that by experiments and observations made according to the principles which have been advanced, a maximum of advantage may be obtained from a ship, as far as the form, the fitness of the proportions and positions of the masts and yards, the proportions of the sails, and the trim of the vessel, will admit; and, what is yet more important, that sufficient data may be obtained to enable the naval architect to judge correctly of the comparative perfection of those means, and so to form correct conclusions as to such deviations from them, as would either tend to their improvement or to obviate similar defects in a future design.

In every vessel a maximum of efficiency.

It is evident, that whatever may be the service required from a vessel, there must always be some maximum of efficiency with reference to those services, which is to be arrived at by a judicious combination of the powers of the vessel with the means which call them into action. The distinguishing division of the characteristics of the qualities required in vessels are mainly those peculiar to burden and those peculiar to velocity. In England, for the last century, we may say that burthen, to the sacrifice of every other quality, nay, even to an extent compromising the safety of the vessel and the lives of the crew, has been the solitary requirement in the design of a merchant-ship.

Distinct qualities, burthen and velocity.

In ships of war both necessary.

In ships of war, under almost all circumstances, it is a combination of the two which is the desideratum; and it is not sufficient that a vessel should be only capable of great velocity in direct courses, or when the propelling force acts in the direction of the keel; for it is in most cases of more importance that she should be capable of great velocity when acted upon by a force in a direction oblique to that of her length, and at the same time that the deviation of her course from this line should be the least possible.

Lee-way.

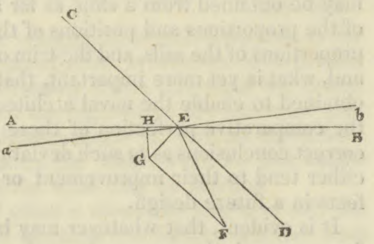
The principles on which this deviation of the course of a ship from the line of her keel, or the angle of lee-way, depends, will now be explained; and the causes will be shown which occasion the actual results of observations on ships to differ from the theoretic principles which have been advanced by writers on this subject; and such methods will be suggested for making further observations in reference to these qualities as may be desirable, with a view to collect data to supply the deficiencies resulting to the theory from the imperfect state of our knowledge respecting the resistances of fluids, particularly as they affect the oblique passage of a ship through the water.

Effective force of wind.

Whatever may be the angle which the direction of the wind makes with the plane of the sails, the only effective force of the wind on the sail is that part of the whole force which can be resolved into a direction perpendicular to the surface of the sails; therefore, whatever may be the whole force of the wind, its effective force will vary as the sine of the angle which the direction of the wind makes with the sail; and as the velocity of the ship is in proportion to the effective force of the wind, it will also, all things else remaining the same, vary as the sine of this angle. Now, as, when the ship is under sail, the direction of its motion should coincide with the middle line, that is, with the direction of the keel, since the plane of resistance is less when the ship moves in that direction than it is when the line of motion cuts the ship obliquely, all that part of the force of the wind which acts in any other direction than that of the keel must be disadvantageous to her progress, as tending to force her in a direction in which she will meet with an increased resistance from the water. From what has been said above, this injurious tendency must necessarily occur in every circumstance of the action of the wind on the sails of a ship, excepting in that under which the trim of the sails is at right angles to the middle line of the ship, as, under all circumstances, the force of the wind on the sail may be resolved into two, both of which will have effect on the ship, the one acting perpendicular and the other parallel to the middle line: or, if we suppose AB (fig. 9) to be the middle line of a ship, and CD the direction of the yard, making with AB the angle DEB less than a right angle; and suppose FE to represent the quantity and direction of the force of the wind; from E and F draw EG perpendicular and FG parallel to DC, and from G draw GH perpendicular to AB; then GE will represent the effective force of the wind on the sail, and GH and HE will be respectively equal to the parts of that force employed in propelling the vessel in a lateral and in a direct course. If CD, the direction of the yard, were perpendicular to AB the line of the keel, the lateral effort of the wind, or the force GH, would be lost, and have no effect on the ship; but when CD is oblique to AB, whatever may be the quantity or direction of the force FE of the wind with respect to AB, it may be resolved into two forces, both of which will be effective on the ship. As long as DEB, the angle formed by the direction of the yard with the line of the keel, remains the same, its complement, the angle GEH, will remain the same; and as GHE is a right angle, the triangle GEH will remain similar to itself, and the proportion between GH and HE will be invariable, and therefore the effort to cause the deviation of the course from the line of the keel, or the action of the force GH, will be in an invariable proportion to the force acting to propel the vessel along that line, or the force HE; and, as we know from what has been before said, that the forces GH and HE must be respectively equal to, and opposed by, the lateral and direct resistances of the water acting in the directions HG and EH, the motion of the ship must be along some line *ab*, such that the equilibrium between these forces may be maintained. This is the principle on which the deviation of the course of the ship from the line of the direction of the keel depends.

Investigation of the angle of lee-way.

Fig. 9.



The angle of lee-way is determined as follows: Suppose the direct and lateral resistances of the water to the passage of the vessel to be respectively R and *r*, and the surfaces respectively opposed to these resistances to be *d* and *e*, and the angle DEB which the sail makes with the line of the keel to be *c*; then, if the angle of lee-way be supposed to be *x*, we have

$$R : r :: d \cdot \cos.^2 x : e \cdot \sin.^2 x$$

$$\therefore \frac{R}{r} = \frac{d \cdot \cos.^2 x}{e \cdot \sin.^2 x} = \frac{d}{e \cdot \tan.^2 x},$$

$$\text{and } \frac{R}{r} = \frac{EH}{HG} = \frac{\sin.\ c}{\cos.\ c} = \tan.\ c$$

$$\therefore \frac{d}{e \cdot \tan.^2 x} = \tan.\ c;$$

$$\text{or, } \tan.^2 x = \frac{d}{e} \text{cotan. } c$$

$$\tan.\ x = \sqrt{\frac{d}{e} \text{cot. } c}.$$

From this equation, also, it appears that the angle of lee-way depends wholly on the angle of inclination of the sail to the line of the keel, without in any way involving the velocity of the ship; and most writers on naval architecture have in this manner considered the question of the equilibrium which exists between the force of the wind and of the resistance of the water in producing this angle. Bouguer has calculated an elaborate table of the angles of lee-way for various classes of ships for the several degrees of inclination of the sail to the keel, from 30° to 90°; but the results which he has obtained differ essentially from those derived from observation on the actual performances of vessels.

Bougue

According to the theory which has been explained, and on which Bouguer founded his calculations, the lee-way depends solely on the angle formed by the yard and the keel, and is uninfluenced by any other cause, and therefore is neither affected by the angle which the direction of the wind makes with the sail, nor by the velocity of the vessel; but this is contrary to the facts elicited by the experience of the actual motion of a ship under sail. From the geometrical construction which has been given, it is evident, that whatever may be the force or the direction of the wind, the proportion which GH bears to HE will increase as the angle DEB diminishes, and so far the theory agrees with experiment; but it is well known to all who have observed the motion of a vessel through the water, that without any alteration in the direction of the wind with the keel, the lee-way varies with every variation in the velocity of the vessel; and also, from this same cause, the alteration in the velocity, all things else remaining the same, if the angle formed by the direction of the wind with the keel be altered, the angle of the lee-way will also experience an alteration; in fact, so greatly does the angle of lee-way depend on the velocity of the ship, that in the same vessel, under similar circumstances of bracing of yards and direction of wind with the keel, the only varying circumstance being a difference in the force of the wind, the quantity of lee-way will vary from that which would occur by the ship's almost drifting in the direction of the sine of the angle of incidence of the direction of the wind on the sail, to that which would exist if her course almost coincided with the line of her keel, or to a quantity which, in practice, would evidently be scarcely observable.

Ex - me t va- riar with the ;

There is some difficulty in accounting for this difference between the results of theory and the facts observed from experience. It depends in a great measure on the imperfection of our knowledge respecting the laws of the motion of bodies in fluids, so that we are unable to estimate the circumstances of the resistance of the water on the bows and on the sides of the ship. The results of the theory of resistances, when applied to oblique impulses, vary very considerably from the actual resistances as observed by experiment, more especially as the angles of incidence become more acute. This discrepancy affects the lateral resistance, or the resistance on the broad-side, more than the direct, or that experienced by the bows of the vessel, and therefore has a corresponding influence in causing the actual lee-way of a ship to differ from the theoretic result. But this, again, is one of those difficulties arising from the imperfect state of the theory of resistances, which may be classed among those which were referred to in the early part of these observations, as requiring "only to be fully known and understood, to be, if not absolutely theoretically solved, at least, from the collection of facts, from experiment, and from analogy, so far overcome, as to leave nothing to be desired." The course of these remarks will tend to show the possibility of this. Professor Robison, in the excellent article on Seamanship, speaking of the results deduced by Bouguer, says, "that the person who should direct the operations on ship-board in conformity to the maxims deducible from M. Bouguer's propositions, would be baffled in most of his attempts, and be in danger of losing his ship. The whole proceeds on the supposed truth of that theory which states the impulse of a fluid to be in the proportion of the square of the sine of the angle of incidence, and that its action on any small portion, such as a square foot of the sails or hull, is the same as if that portion were detached from the rest, and were exposed singly and alone to the wind and water in the same angle....But let it be observed, that the theory is defective in one point only; and although this is a most important point, and the errors in it destroy the conclusions on the general propositions, the reasonings remain in full force, and the *modus operandi* such as is stated in the theory."
